Housing First or Treatment First? Ask the Kids, Not the Parents*

Shahar Rotberg†

November 6, 2026

Abstract

Should housing assistance require sobriety? A general-equilibrium model of homelessness, drug use, drug prices and mortality is calibrated to US data. Use concentrates among low-income households because a substance use disorder's mortality risk, unlike its unemployment risk, is uninsurable. Drug use harms users' children, cutting their consumption and, through a parent's disorder, their adult earnings. In the long run, sobriety conditions reduce these harms and, in aggregate, also childhood homelessness. Consequently, a newborn's welfare rises by 2.57 percent of lifetime consumption, and in general equilibrium parents gain too. The gain reflects an externality, since parents count children only in part, and a missing market, since children cannot pay parents to abstain. Along the transition, homelessness does not rise and newborns still gain. As in randomised controlled trials, users with a disorder lose, but effects on other households and children overturn the verdict. Moral hazard alone does not justify conditionality.

Keywords: homelessness; housing vouchers; substance use disorder; intergenerational spillovers; externalities.

JEL classification: I18; I38; H23; R21; J62.

1 Introduction

According to the point-in-time (PiT) count of January 2024 performed by the Department of Housing and Urban Development (HUD), at least 771,480 people were sleeping in shelters or on the street, the most since the count began. In July 2025 an executive order directed the federal agencies to end support for Housing First policies that, in its words, "fail to promote treatment, recovery, and self-sufficiency".[1] Housing First gives low-income households housing assistance with no requirement to stop using drugs; the alternative, Treatment First, makes the assistance conditional on sobriety and, for those with a substance use disorder (SUD), on being in treatment as well. The funding notice that HUD issued after the order would have capped permanent housing, through which most Housing First assistance is given, at 30 percent of renewal funding, down from more than 80 percent, and would have opened the rest to transitional housing that can require treatment and sobriety, if not for a federal court striking the notice down.[2]

The debate between Housing First and Treatment First is usually framed as a contest between two behavioural claims about the households who receive the assistance.[3] Critics of Housing First say that unconditional assistance creates moral hazard: it weakens the incentive to stay sober and employed, so drug use and SUD rise, and with them homelessness. The result is a vicious circle, whose cost falls on others who fund the programme. Critics of Treatment First say that conditionality delays stable housing for those who need it most, because recovering while homeless is harder. In their argument the circle runs the other way, from homelessness to more SUD and back, so Housing First in fact improves the budget. Randomised trials of Housing First speak to both claims: they find large gains in housing stability and mixed-to-null effects on drug use (Section 2). However, they follow the participants for at most three years, and none follows the children into adult life, tracks households outside the trial, or measures the effect on the government's budget, and only one small trial, of homeless adults already in treatment, compares a sobriety condition with unconditional housing (Milby et al., 2005). A model can do all four.

I weigh in on the debate by building a quantitative life-cycle model in which households decide whether to use drugs knowing the risk of acquiring a SUD, and in which drug use harms not only the user but also the user's child. I begin by showing that the moral hazard that dominates the debate does not drive the answer at all: I remove the externalities that harm children, leaving only the change in behaviour and its impact on the budget. A newborn is then worse off in the long run under Treatment First, by 1.09 percent in consumption-equivalent terms, even when drug use and SUD fall substantially and what the drug test saves on vouchers, together with the higher revenues from more employment, is spent on more vouchers for other households. This is because, without externalities, conditionality removes an option from households who weigh the risks of drug use correctly, as the evidence suggests they do (Section 2), and gives them back significantly less through the government's budget than it takes.

I argue that the answer turns instead on the children, through three externalities that a parent takes into account only through imperfect altruism towards the child: two that Housing First leaves in place, and one that many believe Treatment First creates. The two that Housing First leaves in place fall on the user's children. Children share their parents' consumption and dwelling but not the drug, so every unit a parent spends on drugs, and every unit of earnings lost while a SUD keeps the parent unemployed, is consumption and housing the child goes without: the *budget externality*. Furthermore, a child whose parent had a SUD while the child lived at home starts adult life with lower productivity: the *earnings externality*. The one that many believe Treatment First creates runs through homelessness. By denying assistance to drug users, Treatment First exposes more of them to the shelter, and a child lives wherever its parent lives: the *childhood homelessness externality*. However, I show that, in fact, Treatment First reduces this externality as well.

Whose children bear these costs depends on who uses drugs. Use is concentrated at the bottom of the income distribution: the average user's income is about 74 percent of the population average, and most households do not use at all. The economics literature has reproduced the two facts together only by letting preferences for the drug differ by education (Greenwood et al., 2025). I model drugs as a luxury good bought at a price, which puts most households at a corner where they consume none. On its own, that would concentrate use at the *top*. What reverses the income gradient is the higher risk of dying due to a SUD. This is because the cost of death rises with income and, unlike losing one's job, is uninsurable. The model therefore explains both facts without assuming systematic differences in preferences.

I proceed with two models of rational forward-looking households. The first is a stylized model with two periods of life, in which a SUD raises the risks of dying and of unemployment. Its sole purpose is to show why the income gradient in drug use reverses. The second is a quantitative general-equilibrium life-cycle model calibrated to the United States. Its purpose is to test whether Treatment First raises or lowers welfare relative to Housing First, and whether moral hazard or the externalities on children drive the answer. Its key ingredients are a housing market and homelessness; rationed, means-tested vouchers; income and unemployment risk, with unemployment insurance and food assistance; retirement and social security; recovery and treatment; serious mental illness (SMI); children who share their parent's consumption and dwelling and start adult life with lower productivity if the parent had a SUD during their childhood; a parent's imperfect altruism towards the child; a drug test that misses some users; a drug price that clears

[3]For the case against Housing First as the federal government now makes it, see the executive order cited above, and on its incentives and costs, Eide (2020); for the case for it, see the National Alliance to End Homelessness, `https://endhomelessness.org/blog/ceo-corner-week-of-july-28/`, and on housing stability and costs, Tsemberis et al. (2004) and Larimer et al. (2009).

the drug market; and a government budget whose net revenue is held at its benchmark level through the probability of receiving a voucher.

I use the calibrated model to study how the economy changes when it moves from Housing First, the benchmark, to Treatment First. Under Housing First, housing assistance is unconditional for eligible households who draw a voucher. Under Treatment First, it is conditional on not using drugs and, for those with a SUD, on being in treatment as well. Testing is imperfect, however, so some users go undetected and keep their housing assistance.

The quantitative model lets me separate the three externalities, moral hazard and general-equilibrium effects from one another. I run the same reform with and without the externalities, with only the screen in effect (Treatment First's drug test, which revokes the voucher of a user it catches) and its savings not spent on vouchers, so the one difference between the two runs is whether drug use harms children. Without externalities, with only moral hazard present, a newborn loses 1.17 percent; with them it gains 2.82 percent, childhood included, and the share of children in a shelter actually falls from 1.03 to 0.95 percent. The parents themselves lose about as much whether there are externalities or not. However, with externalities the children gain more than the parents lose. They consume more at home and are less often homeless, and they start adult life without the earnings penalty, all of which are gains their parents only partly count. In the aggregate, then, there is no trade-off between the externalities: by cutting use, the screen keeps more children out of a shelter than it sends to one by putting their parents out. What the *budget, earnings and childhood homelessness externalities* have to outweigh is only the direct loss to the parent from the removal of an option. As I explain below, even the parent gains once general-equilibrium effects are taken into account.

Breaking down the gains from Treatment First, I show that spending the screen's savings on more vouchers raises the gain to 6.45 percent. Letting the drug price clear as well, as it would after a real reform, brings the gain down to 2.57 percent, since the lower drug price draws some households back into use. In this full long-run general-equilibrium exercise, Treatment First cuts drug use by 21 percent and the share of households with a SUD by 19 percent.

A newborn gains 2.57 percent of lifetime non-housing, non-drug consumption (Section 6.1). Three quarters of it is an externality its parent does not count: 1.50 percent of lifetime consumption that the child gets during childhood, and 0.46 percent from entering adult life without the earnings penalty. The rest, 0.62 percent, has two parts. The first, 0.19 percent, is the part of the child's gains that its parent does count. The second, 0.43 percent, is what the newborn gains later, in its own adult life, like any adult living under Treatment First: a voucher that is easier to draw when sober, and a cheaper drug. The parents lose from the screen's direct impact in partial equilibrium, but once general-equilibrium effects are accounted for, they gain as well, by 0.69 percent of their own lifetime consumption. This is the same adult-life gain as the newborn's 0.43 percent, measured from a different starting point. The parents are already adults, and thus do not discount the gain. A newborn gets it only once their childhood is over, so that adult gain is discounted back to birth and thus is smaller. In general equilibrium, then, both the child *and* the parent gain.

The model captures the micro effects that trials measure on the households they follow, and those with a SUD lose from a sobriety condition in the model too. A trial enrols too few households to change the drug price or the chance of drawing a voucher, so the comparison that matches it keeps both at their Housing First levels. Then 74 percent of the households that have a SUD at the time of the reform lose, and when both adjust, 67 percent still do. The macro effects the trials do not observe outweigh these micro effects: on the households the condition deters from starting to use drugs, on the vouchers its savings buy for others, and on children across the economy.

Even along the transition, homelessness and childhood homelessness do not rise, and children born at the reform gain 1.45 percent of lifetime consumption. A concern, especially among critics of Treatment First, is that homelessness and childhood homelessness could rise, since the households that have a SUD when the reform lands face losing their vouchers unless they enter treatment and stay sober. These outcomes actually fall rather than rise, for three reasons. First, few households lose their vouchers: one with a SUD keeps its voucher by entering treatment and not using, and the screen catches only 20 percent of users a year. Second, drug use falls from the first year, so more households spend on housing instead of drugs. Third, the screen's savings fund vouchers for other households, and reduce homelessness and childhood homelessness among them.

Children born at the reform still gain, but less than the 2.57 percent of those born in the long run, for two reasons. First, more of their parents still have a SUD, since the share with one falls only as fast as recovery allows, and a child whose parent has a SUD enters adult life with the earnings penalty, whether or not the parent is in treatment. Second, they grow up before the chance of drawing a voucher has fully risen, since part of what pays for the extra vouchers is the taxes of adults who grew up without that penalty, and those adults are not yet working.

2 Related literature

Randomised trials of Housing First. A large empirical literature evaluates programmes that provide rapid housing without conditioning on sobriety, and finds large and persistent improvements in housing stability and reductions in shelter and other public-service use (Tsemberis et al., 2004; Padgett et al., 2006; Larimer et al., 2009; Goering et al., 2014; Aubry et al., 2016). Evidence on substance use is mixed: most studies find no statistically significant change, and some report modest reductions in alcohol-related outcomes. Costantini (2025) finds that enrolling in Housing First lowers the mortality of homeless veterans with mental illness, while the Treatment First programmes of the Department of Veterans Affairs have no lasting effect on it; Section 5.2 compares the model with this finding. Quasi-experimental evidence from Los Angeles County also finds that housing programmes benefit the people they house. Cohen (2024) finds that placing homeless single adults in housing programmes quickly makes them less likely to return to the homeless support system, lowers crime and reduces their reliance on emergency cash assistance. Brounstein and Wieselthier (2026) find that a two-year rapid rehousing programme raises employment, while permanent supportive housing leaves the employment and earnings of its recipients unchanged. The one trial of homeless families, HUD's Family Options Study, followed 2,282 families for three years: an unconditional subsidy reduced later homelessness, family separations and the children's school absences and behaviour problems (Gubits et al., 2016, 2018).

These studies, however, consider effects on participants over six to thirty-six months, which is a short period of time relative to the recovery process that Vaillant (1995) documents. Moreover, a deeper limitation of a trial is the scope. A trial randomises households within a fixed environment, and thus ignores exactly the effects that in this paper decide the welfare comparison. These are the impact on the behaviour of households outside the sample, the consequences for the government's budget, and, most importantly, the effects on children across the economy, not only those of participants.

Deterrence effects of zero-tolerance policies. The closest evidence on how much a drug test with a severe penalty deters drug use comes from the US military, which in 1981 began testing its personnel at random, 10 to 20 percent of a unit every month, and dismissing those who failed. Mehay and Pacula (1999) use this policy change to compare service members with civilians, following the same people over time. To my knowledge, it is the only study that measures how much such a test deters drug use. They find that drug testing of service members reduced past-year marijuana use by 61 percent. Section 6 uses this response to set how often Treatment First's screen catches a user.

Economic models of drug use. Modelling substance use as forward-looking optimisation dates to Becker and Murphy (1988b), and the assumption is empirically defensible at the margin where policy operates. Use responds to its price, even for drugs as habit-forming as heroin and cocaine, and more in the long run than in the short run, the signature of forward-looking choice rather than myopia (van Ours, 1995; Grossman and Chaloupka, 1998; Saffer and Chaloupka, 1999; Caulkins, 2001; Gallet, 2014). Greenwood et al. (2025), who allow perceived and true SUD risk to differ, find that the model-implied beliefs are actually very close to the true risk. Moreover, young people, if anything, overestimate the risk of becoming dependent, and those who perceive a higher risk drink less (Lundborg and Lindgren, 2002). A separate literature emphasises temptation and dynamic inconsistency (Laibson, 1997; Gruber and Kőszegi, 2001), under which present-biased households over-consume relative to their own long-run preferences. With such assumptions, Treatment First has a rationale even with no externalities at all, since a present-biased household could value a sobriety requirement as a commitment device. Thus, adding dynamic inconsistency to the model

would strengthen the case for conditionality. The paper also departs from Greenwood et al. (2025) in how it generates the income gradient in drug use. There, use concentrates among the less educated because their preferences for drugs differ; here no preference parameter varies with income, and the gradient comes from the uninsurable mortality risk of a SUD (Section 3).

General-equilibrium models of homelessness. I build directly on İmrohoroğlu and Zhao (2022), who model homelessness as a rational response to income risk, mental-health shocks, housing costs and housing policy (see also Abramson, 2026, on how eviction policy changes who becomes homeless, Humphries et al., 2025, on how much rental assistance and delays in eviction court reduce evictions, and Rotberg and Zhang, 2024, on rent control's effect on homelessness). In their framework, the effect of housing policy on homelessness is not tied to drug use, and thus a policy that requires sobriety has no margin to affect. My model includes that margin by adding endogenous drug use, disorder and recovery, along with mortality that depends on a household's state.[4]

Intergenerational transmissions. The *earnings externality* depends on the connection between a parent's SUD and its child's adult earnings. Parental drug abuse is recorded in more than a third of removals into foster care (Adoption and Foster Care Analysis and Reporting System (AFCARS), FY2017), household substance abuse is one of the adverse childhood experiences of Felitti et al. (1998), and children of a parent with a SUD are more likely to acquire one themselves (Mellentin et al., 2016; Yoon et al., 2013). A parent who stays unemployed longer and spends on the drug has less to invest in the child, and that investment shows up in adult earnings: family income raises children's achievement (Dahl and Lochner, 2012), parental investment in education accounts for roughly half of the intergenerational correlation in earnings (Restuccia and Urrutia, 2004), and a year of schooling returns around ten percent (Card, 1999).

Nilsson (2017) is, to my knowledge, the only study that measures, with a natural experiment, how a parental substance shock affects the child's adult earnings. Since this is the best available evidence, the model's productivity penalty is set to its estimate (Section 5), even though the study's shock, exposure to alcohol in the womb, does not map one to one into my model, in which a parent's disorder after the child is born affects the child's productivity. The size of the penalty can also be checked indirectly, by comparing model outcomes to estimates in the literature. In the model, the odds that a child whose parent has a SUD develops one themselves in adulthood are at the low end of the empirical evidence (Section 5.2). This suggests that, if anything, the penalty I use is at the low end as well.[5]

The actual experiment the Nilsson paper uses is as follows. Two Swedish counties allowed grocery stores to sell strong beer for a year in 1967 and 1968. What Nilsson found was that children conceived in the first months of the experiment by mothers under 21 earned 24.4 percent less at age 32 than the cohorts born just before and after them, and than the same cohorts elsewhere in Sweden. Moreover, the loss persisted beyond age 32.

There are two key points to highlight about this study. First, the penalty estimated in Nilsson is an average over the whole exposure group. Specifically, every child a young mother in the two counties conceived during those months counted as exposed, whereas only some of those mothers drank more. Second, the earnings loss is persistent, and this is how I model it. Non-experimental evidence agrees. For example, adult children of problem-drinking parents are more likely to be unemployed and earn less (Balsa, 2008). I do not aim in this paper to offer another estimate, but rather to take the existing estimates as given and to price the effects inside the model.

Homelessness persists across generations too (Bassuk et al., 1997). In the model, this persistence comes from the persistence of earnings, not from homelessness itself. The intergenerational elasticity of earnings in the United States runs from about four tenths (Solon, 1992) to about six tenths (Mazumder, 2005), with the same persistence in ranks across the distribution (Chetty et al., 2014). A poor environment does lower a child's adult earnings beyond that (Chetty et al., 2016; Chyn, 2018), but the model imposes no

[4]The paper does not focus on the disamenity that homelessness may impose on the rest of the population. In a contingent valuation, Loubière et al. (2020) find that Europeans would pay about 0.2 percent of average earnings a year to end homelessness. I also solved the model with a disamenity of that kind, and it barely changes the results. The welfare numbers in the paper leave it out; with it, at that value, no long-run gain in Table 5 moves by more than 0.14 percentage points.

[5]Even when the penalty is set to zero, Treatment First results in welfare gains.

penalty for growing up in a shelter. However, since Treatment First lowers both homelessness and childhood homelessness, and does not raise them even in the short run (Section 6.4), adding such a penalty would only strengthen the case for Treatment First.

Parental altruism towards children. How much of these costs a parent counts depends on the weight it puts on its child. Altonji et al. (1997) reject perfect altruism: when a dollar moves from a grown child to its parent, the parent gives back at most thirteen cents of it. In the model a parent and its grown child do not transfer to each other, so that test cannot be run in it. Instead, the weight is set by behaviour. In the 2024 National Survey on Drug Use and Health (NSDUH), unmarried adults living with one other adult and no child are 17.5 percent more likely to use drugs than lone parents of the same age, sex and family income who have one child. The weight is the one at which removing a parent's concern for its child raises drug use in the model by as much (Section 5). The externality is then the share of what its choices cost the child that the parent leaves out: one minus that weight.

That a drug user has children it affects is supported by the data. Drug users are nearly as likely as others to be parents: in the National Survey of Family Growth 2017–2019, 75 percent of adults aged 40 to 49 who used hard drugs in the past year had a child, against 81 percent of those who used none. They are only somewhat less likely to live with it.[6] Among adults aged 26 to 49, 40 percent of those with a drug use disorder have a child under 18 at home, against 48 percent of comparable adults who used no illicit drug. That gap is too small to matter: even if all of the gain from Treatment First that comes in childhood shrank in proportion to it, the gain would be only 11 percent smaller.[7]

Contracts between parents and children. A child also cannot contract with its parent. Becker and Murphy (1988a) argue that much of what the state does for families, such as public education and support in old age, mimics the agreements that parents and children would reach if children could commit to repay their parents. Boldrin and Montes (2005) show that, when the young cannot borrow to pay for their education, a public system in which the middle-aged finance education and are repaid through pensions restores the allocation of complete markets. Similarly, Rangel (2003) shows that transfers to the old, such as social security, can sustain investment in the young, and Cigno (1993) studies how families sustain transfers between generations without altruism. In my model, the contract that is missing is one in which a child pays its parent to abstain from drugs during its childhood, borrowing against its future income and repaying as an adult. A child can neither borrow nor commit to repay, and the sobriety condition acts as a coarse replacement for that contract.

The hazards and the drug market. Each of the model's hazards is anchored on, or checked against, a clinical or epidemiological estimate: the excess mortality of a SUD, of homelessness and of SMI (Plana-Ripoll et al., 2019; Heiberg et al., 2018; Meyer et al., 2023; Olfson et al., 2015), the onset of SMI and relapse under dual diagnosis (Nielsen et al., 2017; Bradizza et al., 2006), recovery (Vaillant, 1995; Milby et al., 2005), and the employment cost of losing housing (Desmond and Gershenson, 2016). Section 5 takes them one at a time. Making the drug price endogenous lets a policy that changes the number of users change what using costs everybody else. The model's demand elasticities are not calibrated and are compared with the estimates of Saffer and Chaloupka (1999), Grossman and Chaloupka (1998) and Olmstead et al. (2015) in Section 5.2; its supply elasticity is set from Mace et al. (2020) in Section 5.

[6] Users who have a child are less likely to live with it, partly because the state removes children: parental drug abuse is recorded in more than a third of removals into foster care (AFCARS, FY2017), and foster care is itself a very poor environment for a child.

[7] The model likely overstates childhood homelessness, since every homeless parent in the model takes its child into the shelter. The overstatement comes from fathers: a homeless mother's child usually goes with her, but shelters for adult males do not take children, so a homeless father's child usually stays with its mother or other relatives, and some children are taken into foster care.

3 A stylized model

In the data, fewer than one in ten adults have a SUD, mild included, which is what this paper counts as use, and their use is concentrated among people with low incomes: the average user's income is 0.74 of the population average in the 2024 NSDUH. This section shows how both facts can be explained inside a simple economic model of drug use. There are two key ideas. Drugs are a luxury good, so most households consume none of them. And a SUD carries a risk of dying that cannot be insured against, a loss that grows with income, which deters high-income households and not low-income ones and so reverses the income gradient in drug use.

3.1 The model

There are two periods, adulthood and old age, and a continuum of households. A period stands for thirty years of adult life, so the two of them span ages twenty-six to eighty-five. Parameters with a natural annual counterpart are compounded to that length: the discount factor is β per period and $\bar{\phi}$ is survival over thirty years.

A household is characterised by its productivity y, fixed over its life and lognormally distributed across households, $\log y \sim \mathcal{N}(-\frac{1}{2}\sigma_y^2, \sigma_y^2)$, normalised so that its mean is one. Everyone works in the first period. In the second, a household is out of work with probability u_0, or $u_1 > u_0$ if it has a SUD. With $e = 1$ for a household that works and $e = 0$ for one that does not, a household's earnings are $y\,e$: households out of work earn nothing, and there is no unemployment insurance. What a household can do is save, at zero interest, in the first period; it cannot borrow.

The one transfer is food assistance, paid on each period's earnings as

$$F(y\,e) \;=\; \max\{0,\; \bar{c} - \varrho\, y\, e\}, \tag{1}$$

where $\bar{c}$ is the maximum benefit and ϱ the share of earnings by which it is reduced. Food assistance is in the model for one reason. To show the income reversal, Section 3.3 needs to solve the model with saving switched off. A household out of work would then have nothing to consume, which with $\sigma > 1$ leaves its problem undefined; food assistance bounds its consumption from below.

Consumption c and drug consumption v form the bundle

$$X(c, v) = c^{1-\theta}(b + v)^{\theta}, \tag{2}$$

and flow utility is

$$u(c, v) \;=\; U\big(X(c, v)\big) \;+\; \aleph, \qquad U(X) = \frac{X^{1-\sigma}}{1-\sigma}. \tag{3}$$

The weight on the drug θ is its share of the whole, and σ is the coefficient of relative risk aversion.[8] Drugs can be bought only in the first period, at the price p_v. θ and b govern the decision of whether and how much of the drug to consume. The marginal utility of drugs is proportional to $\theta/(b+v)$, which means that θ mostly determines how much a user uses, whereas b affects the decision to use at all. When $b > 0$, the marginal utility of the first unit is finite, so some households do not use. When $b = 0$, the marginal utility from the first unit is infinite and thus every household uses, regardless of the consequences. Finally, $\aleph$ denotes the flow value of being alive unrelated to consumption, and this is what gives life a positive value even when consumption is low.

Using drugs carries the risk of a SUD ($d = 1$ if a household has one and $d = 0$ if not), the same whatever the quantity,

$$\pi(v) \;=\; \pi_d\, \mathbf{1}\{v > 0\}. \tag{4}$$

The whole risk therefore sits on the decision to use at all, not on how much a user uses.[9] Every household enters the first period without a SUD. The SUD is realised at the end of it, and the household survives into the second with probability

$$\phi(0) \;=\; \bar{\phi}, \qquad \phi(1) \;=\; \bar{\phi}^{\,\kappa_{\phi d}}, \tag{5}$$

[8] All the qualitative results of this section hold with log utility as well, with the model recalibrated to the same targets.

[9] The results hold even when I let that probability rise with use.

where a SUD lowers the probability of surviving the period by raising it to the power $\kappa_{\phi d} > 1$. The second period is the last and has no drug-use decision, so to a household with savings a and SUD status d it is worth

$$W(a, y, d) \;=\; (1 - u_d)\, U\big(X(y + a + F(y), 0)\big) \;+\; u_d\, U\big(X(a + \bar{c}, 0)\big) \;+\; \aleph. \tag{6}$$

In the first period, a household that does not use chooses its saving to maximise its lifetime utility,

$$V^0(y) \;=\; \max_{\{a \geq 0\}} \; \Big\{ U\big(X(y - a + F(y), 0)\big) + \aleph + \beta\, \bar{\phi}\, W(a, y, 0) \Big\}, \tag{7}$$

and one that uses chooses its saving and its drug consumption to maximise it,

$$V^1(y) \;=\; \max_{\{a \geq 0,\; v > 0\}} \; \Big\{ U\big(X(y - a + F(y) - p_v v,\; v)\big) + \aleph + \beta \Big[(1 - \pi_d)\, \bar{\phi}\, W(a, y, 0) + \pi_d\, \bar{\phi}^{\,\kappa_{\phi d}}\, W(a, y, 1) \Big] \Big\}. \tag{8}$$

It uses if $V^1(y) > V^0(y)$. A SUD reaches the second period through two channels: the mortality channel, which lowers the chance of living it, and the unemployment channel, which raises the chance of living it unemployed.[10]

3.2 Calibration

Here, I calibrate the model. Table 1 lists the parameters I assign externally, and Table 2 lists the ones I assign internally. All five internally fitted parameters are determined jointly, but each is calibrated based on the moment it affects the most. The model hits all the moments exactly. I created a replication package (`data/DATA_APPENDIX.md`), which provides every target and the dataset used to compute it (with its year and universe). Below I give each moment and its source.

3.2.1 External calibration

Preferences and demographics are conventional: the discount factor over a thirty-year period is $\beta = 0.86$, which is 0.995 a year compounded,[11] and risk aversion is $\sigma = 2$, as in the quantitative model. Survival over a period, the cumulative chance of surviving from age twenty-six to age fifty-five, is $\bar{\phi} = 0.93$, from the life table for the total population of the United States in 2010 (Arias, 2014). The chance that use causes a SUD, $\pi_d = 0.41$, is set so that the ratio of the SUD rate to participation matches the data in the 2024 NSDUH, 3.68 against 8.90 percent of adults aged 26 and over.

The dispersion of log productivity σ_y is set so that the poorer half of the lognormal holds 17.2 percent of total income, the share of earnings held by the poorer half of households aged 26 to 65 with positive wage and salary income in the 2022 Survey of Consumer Finances (SCF). In the second period, a household without a SUD is out of work with probability u_0, 4.9 percent, the average unemployment rate from 2014 to 2024, and one with a SUD with probability u_1, 16.2 percent, the unemployment rate of adults aged 26 and over with a SUD in the 2024 NSDUH. Food assistance tapers at $\varrho = 0.30$, the benefit reduction rate of the Supplemental Nutrition Assistance Program (SNAP), and the price of a unit of drugs p_v is normalised to one.

3.2.2 Internal calibration

The flow value of being alive $\aleph$ is matched to a value of a statistical life (VSL) of 80 times average annual income (Viscusi and Aldy, 2003).[12] The parameter b, which sets the marginal utility of the first unit of

[10] The results in Section 3.3 also hold in a version of this model with housing, a shelter, unemployment insurance and housing vouchers. There, if a SUD has no consequences, the average user earns 3.54 times the population average; the risk of dying, on its own, takes this to 0.52 at twice its calibrated strength, while the risk of losing one's job, on its own, leaves it at 3.54. In contrast, after switching off the savings option, the risk of losing one's job brings it down to 0.56 on its own.

[11] The annual discount factor here is higher than the one in the quantitative model, and this is deliberate. A model period is thirty years. This means that the consequences of using drugs arrive only thirty years after the decision. Therefore, with a low discount factor, the risk of death in the distant future would be heavily discounted and dominated by impatience. I therefore apply a higher factor in the stylized model to correct for the coarseness of the horizon. In the full quantitative model, in contrast, the consequences of using drugs are annual, and thus a lower calibrated discount factor is not an issue.

[12] No household has a negative value of life in period 1, so death is never an optimal choice.

Table 1: Externally set parameters

Parameter	Description	Source or rationale	Value
β	Discount factor over a thirty-year period	0.995 annually, compounded	0.86
σ	Risk aversion	Standard; Attanasio and Weber (2010)	2
$\bar{\phi}$	Survival over a period, no SUD	US life table 2010, Arias (2014), ages 26–55	0.93
π_d	Chance that use starts a SUD	NSDUH 2024: SUD rate over participation	0.41
σ_y	Dispersion of log productivity	SCF 2022: bottom half holds 17.2% of earnings	0.95
u_0	Unemployment rate in period 2, no SUD	BLS CPS, average 2014–2024	0.049
u_1	Unemployment rate in period 2 with a SUD	NSDUH 2024, ages 26 and over	0.16
ϱ	Food assistance taper	SNAP benefit reduction rate	0.30
p_v	Price of a unit of drugs	Normalisation	1.00

Table 2: Internally calibrated parameters

Parameter	Target moment	Data	Model	Value
$\aleph$	VSL over income	80	80.0	8.64
b	Drug participation, NSDUH 2024	8.9%	8.9%	0.032
θ	Drug spending over users' income	16.0%	16.0%	0.22
$\kappa_{\phi d}$	Users' income over the average, NSDUH 2024	0.74	0.74	3.56
$\bar{c}$	Food assistance over labour income	0.42%	0.42%	0.10

drugs, is chosen to match a drug participation rate of 8.90 percent, the share of respondents aged 26 and over in the 2024 NSDUH with a drug use disorder of any severity. The weight on drugs θ is set to match the aggregate drug spending over the aggregate income of users, 16.0 percent, from retail spending in Midgette et al. (2019) and the incomes of users in the 2024 NSDUH. The level of food assistance $\bar{c}$ is set so that total food assistance is 0.42 percent of total labour income, the ratio of SNAP outlays to gross domestic product (GDP).

The mortality exponent $\kappa_{\phi d}$ is set to match the average income of users, 0.74 of the population average in the 2024 NSDUH, because the death risk is what decides how far down the income distribution use sits, as Section 3.3 shows.

3.3 Who uses drugs

Drugs in the model are a luxury good bought at a price, so a household with twice the income gives up less utility per dollar spent on them. Without consequences of using drugs, drug use would concentrate at the top of the income distribution. With b recalibrated so that participation stays at 8.90 percent, the average user would earn 3.51 times the population average. I spend the rest of this section showing that it is the uninsurable risk of dying that puts drug use at the bottom of the income distribution.[13]

In Figure 1, I vary the strength of each of the two penalties, mortality and unemployment. I start from zero and run up to 200 percent of each of their calibrated values, keeping the other penalty switched off. I scale $\kappa_{\phi d} - 1$ for the mortality channel and $u_1 - u_0$ for the unemployment channel. I recalibrate b each time to keep participation at its calibrated value. This means that the share of households that use is the same across the figure, and what changes is only who uses.

The left panel shows the calibrated model, in which households can save. The mortality channel alone takes the average user from 3.51 times the population average down to 0.64 at its calibrated strength, crossing the average at 73 percent of that strength, and to 0.27 at 200 percent.[14] In contrast, the unemployment channel alone leaves the average user at 3.51 times the population average even at 200 percent: on its own it does not change who uses at all.

The right panel shows that when the precautionary savings are switched off, both the risk of dying and the risk of losing one's job reverse the income gradient. Without savings, the unemployment channel on its own takes the average user to 0.75 times the population average at its calibrated strength, and to 0.27 at

[13] A household can buy life insurance, but it protects its descendants, not the household itself or the value of its own life.

[14] With both channels at their calibrated strength, the average user earns 0.74 times the population average, as in the data.

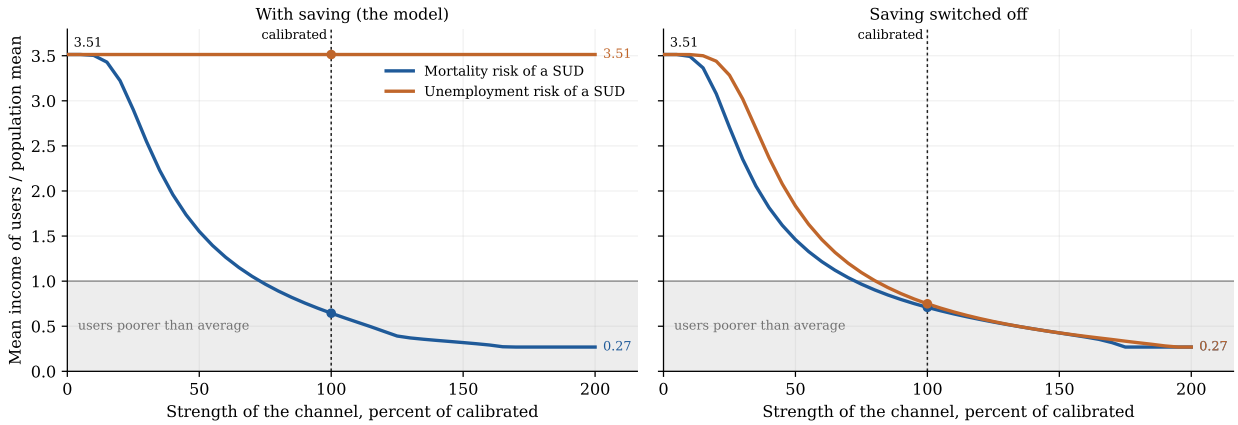

Figure 1: What it takes to reverse the income gradient in drug use

Notes: each curve scales one channel with the other switched off. Left: the model. Right: the same parameters with saving switched off. The vertical axis is average income of users over the population average, and b is recalibrated at every point so that participation is the calibrated 8.90 percent. The vertical dotted line marks the calibrated strength.

200 percent.

Who uses depends on two things that vary with income. The first is the cost of acquiring drugs, and the second is the penalty drugs inflict. The utility cost of the drug falls with income, because a household with more income gives up less marginal utility for each dollar it spends on drugs. Therefore, ceteris paribus, drugs cost a rich household less than a poor one.

The penalty inflicted by drugs does not rise with income when it can be partially insured against, but does rise when it cannot be. A richer household can save more to protect itself in the event of unemployment. Thus, its loss is roughly proportional to its income. As a result, in utility terms, the cost of losing its employment is about the same as the cost imposed on a poor household. Death, on the other hand, cannot be insured against. Dying eliminates the full continuation value of being alive, and that loss grows with income, so it deters high-income households but not low-income ones. Without the ability to save, losing a job takes a household down to $\bar{c}$ whatever it earned, so that loss too grows with income, which is why in the right panel the unemployment channel reverses the gradient as well.

4 The quantitative model

This section describes the model the paper's numbers come from. It keeps the preferences of the stylized model of Section 3 and the two risks a SUD brings there, and adds what that model leaves out: housing, homelessness and vouchers; annual periods; unemployment insurance; income risk during working age; retirement; progressive income taxes; interest on savings; a drug-use decision in every year; recovery and treatment; SMI; a higher risk of dying, worse employment prospects and a lower chance of recovering while homeless; children who live with their parents; a drug test that misses some users; a government budget held at its benchmark net revenue; and an endogenous drug price. Notation follows Section 3 wherever the two models share an object: θ is the drug weight, σ the risk aversion, b the Stone–Geary shifter, $\aleph$ the flow value of being alive, π_d the chance that use starts a SUD, $\kappa_{\phi d}$ the mortality multiplier for the disorder, p_v the drug price and β the discount factor. The values are in Section 5.

4.1 Demographics and the state and choice sets

At model age $j = 1$, a child becomes an adult, leaves its parent's home, joins the workforce and forms its own household, with a child of its own. The household lives at most J annual periods, works while $j < J_R$ and is retired from J_R. Its child lives with it for the first J_K years and then leaves to form its own household in turn.

Each period a cohort of unit mass enters at $j = 1$, made up of the children who leave home that period, at their parent's death if that comes before J_K and at J_K otherwise (equation (29)). It replaces the mass of the households who died, so the mass of households is constant in a stationary equilibrium. The individual state is age j together with

$$s = (a,\, y,\, e,\, d,\, m,\, \eta) \in \mathbb{R}_+ \times \mathcal{Y}(j) \times \{1,2,3\} \times \{0,1,2\} \times \{0,1\} \times \{0,1,2\}, \tag{9}$$

where a denotes assets, y productivity, e employment status, d the SUD, m SMI and η the household's standing with the voucher programme. The SUD takes three values because the parent's valuation of its child's prospects depends on the history of the disorder and not only on its present (Section 4.10): $d = 0$ denotes a household that has never had the disorder, $d = 1$ refers to one that had it and has recovered, and $d = 2$ stands for one that has it now.[15] The voucher state is $\eta = 0$ for a household without a voucher, $\eta = 1$ for one that holds one, and $\eta = 2$ for one excluded from the programme after failing Treatment First's condition (Section 4.9).

Each period the household chooses the bundle

$$\big(h,\, v,\, \tau,\, a'\big) \in \{h_1, h_2, h_3, h_4\} \times \mathbb{R}_+ \times \{0,1\} \times \mathbb{R}_+, \tag{10}$$

where h is the dwelling, of which h_1 is a shelter, v is drug consumption, τ is whether or not the household is in treatment for the SUD, available only to a household that has the disorder, and a' is its next period's assets. Labour is inelastically supplied when employed.

4.2 Preferences

Flow utility is the stylized model's, with housing in the bundle and the child present for the first J_K years. Consumption c and housing h are shared through the equivalence scale $\xi(j)$, which counts two members while the child is at home and one after. The drug enters the parent's utility alone, so the parent and the child hold the bundles

$$X_P = \Big[\Big(\frac{c}{\xi(j)}\Big)^{1-\gamma}\Big(\frac{h}{\xi(j)}\Big)^{\gamma}\Big]^{1-\theta}(b+v)^{\theta}, \qquad X_c = \Big[\Big(\frac{c}{\xi(j)}\Big)^{1-\gamma}\Big(\frac{h}{\xi(j)}\Big)^{\gamma}\Big]^{1-\theta} b^{\theta}, \tag{11}$$

and period utility is

$$u\big(c,h,v,\tau\big) \;=\; U(X_P) \;+\; \omega_c\,(\xi(j)-1)\,U(X_c) \;+\; \aleph \;-\; \tau\,\bar{\tau}^{u}, \qquad U(X) = \frac{X^{1-\sigma}}{1-\sigma}. \tag{12}$$

γ is housing's share of the non-drug bundle and θ the drug's share of the whole, σ is the coefficient of relative risk aversion, $\aleph$ is a flow value of being alive, counted once per household, and $\bar{\tau}^{u}$ is the utility cost of a year in treatment, which is described in Section 4.6. The child's term is its own flow utility, counted as $\xi(j) - 1$ of the household and weighted by the parent at ω_c. The child gets none of the drug, so a parent's drug spending reaches it through a reduction in the consumption and housing they share.

4.3 Income, taxes and transfers

Productivity. Log productivity follows a persistent process over working life, $\log y_{j+1} = \rho_y \log y_j + \zeta_{j+1}$ with $\zeta \sim \mathcal{N}(0, \sigma_\zeta^2)$, and is held fixed at its last working value in retirement. When employed, a household earns $y\,\varepsilon(j)$. The term $\varepsilon(j)$ is a deterministic age profile, and y is normalised such that it averages one upon entry. A household inherits its productivity at entry from its parent, and a child who enters with the penalty keeps a lower productivity throughout their life. I explain the intergenerational transmission in detail in Section 4.8.

[15] Section 3 wrote $d \in \{0,1\}$ for the disorder absent and present; here $d = 1$ is a household that has recovered, since the quantitative model keeps the history.

Before-tax income. Before-tax income depends on age and employment,

$$\tilde{y}(j,y,e) = \begin{cases} y\,\varepsilon(j) & j < J_R,\ e = 1 \quad \text{(employed)} \\ \psi_{ui}\,\min\{y\,\varepsilon(j),\ \bar{y}\} & j < J_R,\ e = 2 \quad \text{(insured, first year out of work)} \\ 0 & j < J_R,\ e = 3 \quad \text{(out of work, uninsured)} \\ S(y) & j \geq J_R \quad \text{(retired)}. \end{cases} \tag{13}$$

Unemployment insurance (UI) replaces a share ψ_{ui} of earnings on a base capped at $\bar{y}$, and it is paid only to a share p_{ui} of those losing their job, mimicking the share of insured separations. After the first year, unemployed households, insured and uninsured alike, receive zero UI ($e = 3$). Social security $S(y)$ follows the statutory formula.[16]

The SUD and SMI act on whether the household is employed, through the employment transitions below. There is no disability insurance in the model, so SMI brings no income of its own.[17]

Taxes. Before-tax income is taxed with the Heathcote et al. (2017) function and capital income at a flat rate, so that after-tax income is

$$y^n = \min\left\{\tilde{y},\ \tau_\ell\,\tilde{y}^{\varphi}\right\} \ +\ (1-\tau_k)\,r\,a, \tag{14}$$

where τ_ℓ scales after-tax income and so sets the level of the tax, which falls as τ_ℓ rises, and $1-\varphi$ sets its progressivity. The flat tax rate on capital income is τ_k, and r is the exogenous interest rate on savings.[18]

Transfers. Food assistance pays the maximum allotment $\underline{c}$ less the share ϱ of income. The voucher pays a holder that is eligible this period the part of its rent above a tenant contribution of κ_r of income, up to the fair market rent (FMR),

$$\begin{aligned} F &= \max\left\{0,\ \underline{c} - \varrho\,\hat{y}\right\}, \\ Vch &= \mathbf{1}\{\eta = 1\}\,\mathbf{1}\{\hat{y} < \kappa_V y^{\text{med}}\}\,\mathbf{1}\{h \neq h_1\}\,\min\Big\{\max\{0,\ p_r h - \kappa_r \hat{y}\},\ \max\{0,\ FMR - \kappa_r \hat{y}\}\Big\}, \end{aligned} \tag{15}$$

where $\hat{y} = \tilde{y} + ra$ is the income both programmes are means-tested on, κ_V and median income y^{med} are the eligibility rule in Section 4.9, and FMR is the average rent paid by housed households in the benchmark. A voucher holder in a shelter keeps the voucher and is paid nothing until it rents again, as long as it keeps its eligibility.

Each entering household receives a one-time endowment T_0 from bequests left by deceased households, and the government collects the rest of the estates of the dead.

4.4 The budget constraint

The household's budget constraint is as follows:

$$c + p_v v + a' \ =\ y^n + a + T_0\mathbf{1}\{j=1\} \ -\ p_r\,h\,\mathbf{1}\{h \neq h_1\} \ +\ Vch + F, \qquad c \geq F,\ v \geq 0,\ a' \geq 0. \tag{16}$$

Food assistance is paid in kind, so it cannot directly fund the drug, the rent or saving. The drug price is p_v, which is endogenous, whereas the rent per unit of housing p_r is fixed and held at its benchmark value in every simulation.[19] Treatment costs the household utility only; the government pays for it (see Section 4.11).

[16] Let $y^s = \min\{y,\, y^{\max}\}$ denote the household's productivity at its last working age up to the taxable maximum $y^{\max}$, the ceiling above which earnings no longer raise the benefit. Then social security payments are $S(y) = \bar{w}\max\left\{\underline{S},\ \alpha_1\min\{y^s, k_1\} + \alpha_2\max\{0, \min\{y^s, k_2\} - k_1\} + \alpha_3\max\{0, y^s - k_2\}\right\}$, where $k_1 < k_2$ are the two bend points, $\alpha_1 > \alpha_2 > \alpha_3$ the shares replaced below, between and above them, $\underline{S}$ the Supplemental Security Income (SSI) payment, and $\bar{w}$ the benchmark's average labour income. Their values are given in Appendix A.

[17] In the data only a minority of adults with SMI receive disability benefits on the basis of a mental disorder: about 3 million, through Social Security Disability Insurance or SSI, against 14.6 million adults with SMI in NSDUH 2023, roughly one in five.

[18] The minimum keeps the labour income tax from turning negative, since at low incomes $\tau_\ell\tilde{y}^{\varphi}$ exceeds $\tilde{y}$ itself.

[19] In earlier versions of this work, I solved the model with endogenous labour supply, rents, homeownership and house prices. These margins turned out to have a negligible effect on the results, so for conciseness I removed them and hold the rent fixed.

4.5 Housing and the homelessness loop

Housing is the four-point grid of (10): h_1 is literal homelessness, sleeping rough or in an emergency shelter, which is free, and $h_2 < h_3 < h_4$ are three rental sizes. Homelessness raises mortality (20), worsens both employment margins (21) and lowers the chance of recovering from the SUD (18), but does not affect SMI (Section 4.7).

4.6 Drug use, the SUD, recovery and treatment

A household that does not have the disorder, either $d = 0$ (never had it) or $d = 1$ (had it but recovered), acquires it ($d = 2$) with probability π_d if it uses,[20]

$$\Pr(d' = 2 \mid d \neq 2,\, v) = \pi_d \, \mathbf{1}\{v > 0\}, \tag{17}$$

and a household that has recovered can acquire the disorder again. A household may begin using only up to an age J_E.[21] A household with the SUD recovers, to $d = 1$, with probability

$$\begin{aligned} \pi_r(h, m, \tau) = \min \Big\{ 1,\; \bar{\pi}_r \left(\mathbf{1}\{h = h_1\} \, \mu_H + \mathbf{1}\{h \neq h_1\} \right) \left(\mathbf{1}\{m = 1\} \, \mu_m + \mathbf{1}\{m = 0\} \right) \\ \times \left(\mathbf{1}\{\tau = 1\} \, g + \mathbf{1}\{\tau = 0\} \right) \Big\}, \end{aligned} \tag{18}$$

where $\bar{\pi}_r$ is the baseline annual chance of recovering while housed, without SMI and untreated. Three multipliers affect it. Recovery is harder when homeless ($\mu_H < 1$) as well as with SMI ($\mu_m < 1$), but is more likely in treatment ($g > 1$).

Households who go to treatment τ pay a utility cost $\bar{\tau}^u$, shown in (12). What they gain is a higher chance of recovery, with $g > 1$. Treatment does not require a household to stop using, but as long as the disorder remains, it still raises the risk of mortality.

4.7 SMI

m is a two-state Markov chain representing SMI, mental illness severe enough to cause substantial functional impairment. It affects a small share of adults, whereas any mental illness affects roughly a quarter of adults and includes mild anxiety. Onset follows an age profile $\varsigma_m(j)$, normalised to one at age 26 and scaled by the level ω_m, and a household that carries the SUD is $\iota > 1$ times more likely to develop SMI than one that does not,

$$\Pr(m' = 1 \mid m = 0, d) = \min \left\{ 1,\; \omega_m \, \varsigma_m(j) \left(\mathbf{1}\{d = 2\} \, \iota + \mathbf{1}\{d \neq 2\} \right) \right\}, \qquad \Pr(m' = 0 \mid m = 1) = \lambda_m. \tag{19}$$

A household with SMI recovers from it with the probability λ_m each year, whatever its housing and whether or not it carries the SUD.

SMI then affects three objects: the chance of finding a job when unemployed, through (21); mortality, through (20), both in Section 4.8; and the SUD recovery hazard, through μ_m in (18) in Section 4.6. It does not enter the utility function. This is because a SUD makes SMI more likely, so a policy that deters drug use also prevents some SMI. If the utility function changed with SMI, that prevention would raise welfare mechanically, and the policy analysis would partly reflect that assumption. The SMI chain does not depend on housing, because in the At Home / Chez Soi randomised trial, housing had no detectable effect on the symptoms of homeless adults with SMI (Stergiopoulos et al., 2015).

[20] In earlier versions of the model, I allowed the probability of developing a SUD to rise with use, but since it had little impact on the results, I removed it for simplicity.

[21] Without this limit, using at old ages has little-to-no consequence: too little life remains for the disorder to damage, so the model produces too much old-age use. The cause is that death is certain at the last age J, so close to it a household knows how little life remains, whereas in real life the vast majority of people do not know exactly when they will die. The value of J_E is in Appendix A. The limit stops only households without a SUD from starting to use; a household that already has a SUD at that age keeps using.

4.8 What the SUD, SMI, and homelessness cost

Death risk. Write $1-\bar{\phi}(j)$ for the probability of dying at age j of a household that is housed and has neither the disorder nor SMI; the three multipliers below raise it for every other household. Write $q^{0}(j,h)=\min\{1,\left(\mathbf{1}\{h=h_1\}\,\kappa_{\phi H}+\mathbf{1}\{h\neq h_1\}\right)(1-\bar{\phi}(j))\}$ and $q^{1}(j,h)=\min\{1,\kappa_{\phi d}\left(\mathbf{1}\{h=h_1\}\,\kappa_{\phi H}+\mathbf{1}\{h\neq h_1\}\right)(1-\bar{\phi}(j))\}$ for the probability of dying without and with the disorder, respectively. In the stylized model $\kappa_{\phi d}$ was an exponent on the survival probability; here it multiplies the death hazard. The probability of dying is then

$$1-\phi(j,h,d,m)=\min\Big\{1,\ \left(\mathbf{1}\{m=1\}\,\kappa_{\phi m}+\mathbf{1}\{m=0\}\right)q^{0}(j,h)+\mathbf{1}\{d=2\}\big[q^{1}(j,h)-q^{0}(j,h)\big]\Big\}, \tag{20}$$

so $\kappa_{\phi H}>1$ multiplies the death probability when a household is in a shelter, $\kappa_{\phi d}>1$ when a household has a SUD, and $\kappa_{\phi m}>1$ the baseline risk when a household has SMI, to which the excess risk of the disorder is added.

Unemployment risk. A job is lost with probability π^{eu} and found with probability π^{ue},

$$\begin{aligned}\pi^{eu}(y,h)&=\min\Big\{1,\ \bar{\pi}^{eu}\,\varpi(y)\left(1+\mathbf{1}\{h=h_1\}\,\kappa_H\right)\Big\},\\ \pi^{ue}(h,d',m')&=\min\Big\{1,\ \frac{\bar{\pi}^{ue}\left(1-\mathbf{1}\{h=h_1\}\,\kappa_H\right)}{\left(\mathbf{1}\{d'=2\}\,\kappa_d^{ue}+\mathbf{1}\{d'\neq 2\}\right)\left(\mathbf{1}\{m'=1\}\,\kappa_m^{ue}+\mathbf{1}\{m'=0\}\right)}\Big\},\end{aligned} \tag{21}$$

with $\bar{\pi}^{eu}$ and $\bar{\pi}^{ue}$ the baseline separation and job-finding rates, $\varpi(y)$ a factor that makes separations likelier at low productivity, and the divisors κ_d^{ue} and κ_m^{ue} making a job harder to find with the SUD and with SMI. Neither the SUD nor SMI raises separations; each only reduces the chance of regaining employment. κ_H does both for a household in a shelter.

The child's productivity penalty. A child whose parent had the disorder at any point while the child lived at home, before J_K or before the parent died if that came first, starts adult life with its productivity lowered by the proportion δ_d in (22) below, and the penalty stays with the child for life.

A child's log productivity at entry is drawn around its parent's, with persistence ρ. The innovation keeps the spread of productivity at entry the same in every generation. If the parent had the disorder at any point before the child became an adult, the penalty scales the child's productivity down for life:

$$\begin{aligned}\log y_1^{\text{child}}\ &=\rho\,\log y^{\text{parent}}+(1-\rho)\,\mu+\epsilon\\ &\quad+\log(1-\delta_d)\,\mathbf{1}\{\text{parent has } d\geq 1 \text{ when its child becomes an adult}\},\end{aligned} \tag{22}$$

with y_1^{child} the child's productivity in the period it becomes an adult in the workforce ($j=1$), y^{parent} the parent's productivity in the period just before its child becomes an adult, μ the mean of log productivity at entry and ϵ normally distributed with mean zero and variance $1-\rho^2$ times the variance of log productivity at entry. The penalised child's productivity is lower, which means that its own child is also more likely to inherit a lower draw. Through this persistence, the penalty ripples through the whole lineage, and not just the child whose parent had a SUD during their childhood.

4.9 The voucher and the two policies

A household is eligible for a voucher while its income is below the share κ_V of median income,

$$\hat{y}\ <\ \kappa_V\,y^{\text{med}}, \tag{23}$$

with $\hat{y}$ the income of (15). A holder keeps its voucher while it is eligible, and an eligible household without one draws one with probability π_V. Under Housing First that is the whole rule.

Under Treatment First the programme is conditional. A household fails the condition if it uses, $v>0$, or has the disorder and is not in treatment, $d=2$ and $\tau=0$. A household with a SUD must be in

treatment (paid for by the government), as the executive order directs, and no household may use even while in treatment, as the guidance implementing the order requires of drug-free housing.[22]

Income-eligible holders and income-eligible households that draw a voucher are tested, at a cost c_{test} each to the government, and one that fails the condition is detected with probability p_{det}. This means that enforcement is not perfect: with probability $1 - p_{\text{det}} > 0$ a household that fails the condition actually gets to keep its voucher. A detected holder keeps this period's payment and loses the voucher from the next period; a detected applicant never receives it. In both cases, the household is excluded from the voucher programme for a period of time ($\eta = 2$): it cannot draw a voucher whatever its income, and it returns to the lottery ($\eta = 0$) with probability ψ_x each year.

None of p_{det}, ψ_x and c_{test} binds in the benchmark, where no voucher is conditional, so all three are set with the experiment in Section 6 rather than in the calibration.

4.10 The household's dynamic problem

Write $\Gamma\big(s' \mid s,\, h, v, \tau, a'\big)$ for the law of motion of the state that the transitions above define, given the state and the choices. Then, for $j = 1, \ldots, J$ and with $V(J{+}1, \cdot) = 0$,

$$
\begin{aligned}
V(j,s) = \max_{\{h,\,v,\,\tau,\,a'\}} \Bigg\{ & U(X_P) + \omega_c(\xi(j) - 1)\, U(X_c) + \aleph - \tau\bar{\tau}^u \\
& + \ \beta\, \phi(j,h,d,m) \int_{\mathcal{S}} V(j{+}1, s')\, \Gamma\big(\mathrm{d}s' \mid s, h, v, \tau, a'\big) \\
& - \ \beta\, \chi(j)\, \omega_c\, D(y,d) \Bigg\}, \qquad \chi(j) = \begin{cases} 1 - \phi(j,h,d,m) & j < J_K \\ 1 & j = J_K \\ 0 & j > J_K, \end{cases}
\end{aligned}
\tag{24}
$$

subject to the budget (16), the income and transfer rules (13) to (15) in Section 4.3, and the restrictions that treatment is available only to a household with $d = 2$ and that no household begins using after J_E.

The first line is the flow of (12). The second is the household's own continuation. The third is the impact of the parent on the child's adult value, counted only when the child leaves: at J_K with certainty, and before then with the probability that the parent dies first. $D(y,d)$ is what the parent's disorder costs the child, in the child's own lifetime value,

$$
D(y,d) = \mathbb{E}\big[V(1, s_{\text{child}}) \,\big|\, y,\ 0\big] - \mathbb{E}\big[V(1, s_{\text{child}}) \,\big|\, y,\ d\big] \ \geq\ 0, \tag{25}
$$

where the child is valued as it enters at $j = 1$ with the initial states described in Section 4.13, and its productivity is drawn as in (22) in Section 4.8 from a parent with productivity y. In the first term of (25) the parent has never had the disorder, and in the second it has its actual d in the period the child leaves. If it never had a SUD, there is no charge to the parent ($D(y,0) = 0$); if it had a SUD before the child leaves ($d \geq 1$), it is charged ($D(y,d) > 0$).[23]

One weight ω_c multiplies both child terms, the flow of childhood and the value of the child's adulthood. At $\omega_c = 0$ the damage a household does to its child is entirely external; at $\omega_c > 0$ it internalises the share ω_c and only $1 - \omega_c$ remains external.

The policy functions $h(j,s)$, $v(j,s)$, $\tau(j,s)$ and $a'(j,s)$ are the dwelling, drug use, treatment and saving that solve (24) at age j and state s.

[22] Executive Order 14321, Section 5(b); the guidance is *Addressing Homelessness and Addiction through "Treatment First"* (2026), p. 9, issued by the Office of National Drug Control Policy, the Department of Health and Human Services and HUD. The Housing Choice Voucher programme bars admission for current illegal drug use (Code of Federal Regulations (CFR), Title 24, Section 982.553) but does not test; Housing First here is a programme that does not test. The order also encourages the civil commitment of people with mental illness who pose a risk to themselves or others, or who live on the street and cannot care for themselves. In the model, treatment is always the household's choice: a household with a SUD that declines it loses its voucher if the screen catches it.

[23] The term is a difference and not a level. Written as a level, ω_c times the child's value, the term would be worth more to a household the likelier the household is to die, because the death branch carries it. It would then pay most to the households with a SUD, for reasons that have nothing to do with the child. As a difference, the term is zero for a parent who has never had the disorder and a cost otherwise.

4.11 The government

Write $\Phi(j,s)$ for the distribution of the households of age j over the states s; its law of motion is in Section 4.13. The government's budget constraint is

$$\begin{aligned}\mathcal{R} \;=\; \sum_{j=1}^{J} \int_{\mathcal{S}} \Big[\tilde{y}(j,y,e) - \min\big\{\tilde{y}(j,y,e),\, \tau_\ell\, \tilde{y}(j,y,e)^{\varphi}\big\} + \tau_k\, r\, a \\ + \big(1-\phi\big(j,h(j,s),d,m\big)\big)\, a'(j,s) \Big]\, \mathrm{d}\Phi(j,s) \;-\; T_0 \\ - \sum_{j=1}^{J} \int_{\mathcal{S}} \Big[UI(j,y,e) + S(j,y) + F(j,s) + Vch(j,s) + c_{\text{test}}\, \mathbf{1}^{\text{test}}(j,s) + c_{\text{treat}}\, \mathbf{1}\{d=2,\, \tau(j,s)=1\} \Big]\, \mathrm{d}\Phi(j,s).\end{aligned} \tag{26}$$

The first line is revenue from the labour and capital income taxes of (14). The second is the estates of the households who die, which the government collects, less the endowment T_0 it gives the unit mass of entrants. The third is what the government pays: UI, $UI(j,y,e) = \tilde{y}(j,y,e)\,\mathbf{1}\{j < J_R,\, e=2\}$; social security, $S(j,y) = S(y)\,\mathbf{1}\{j \geq J_R\}$; food assistance $F(j,s)$ and the voucher $Vch(j,s)$ of (15), at the household's dwelling $h(j,s)$; under Treatment First, the cost c_{test} of each household tested, $\mathbf{1}^{\text{test}}(j,s)=1$; and, under both policies, the cost c_{treat} of a year of treatment for each household with the SUD that takes it up, $\tau(j,s)=1$, since treatment is publicly funded.

In the benchmark the tax parameters are set as in Section 5 and $\mathcal{R}$ is whatever surplus they produce. In every experiment the taxes are held at their benchmark values, and the probability of drawing a voucher π_V adjusts so that $\mathcal{R}$ equals its benchmark value $\bar{\mathcal{R}}$, unless the experiment fixes π_V.

4.12 The drug market

The price of the drug clears its market,

$$p_v = \nu_1 S_v^{1/\varepsilon_s}, \qquad S_v = \sum_{j=1}^{J} \int v(j,s)\, \mathrm{d}\Phi(j,s), \tag{27}$$

where ε_s is the price elasticity of supply and ν_1 is normalised so that the price is one in the benchmark, and then held fixed across experiments.[24]

4.13 The law of motion

Given the policy functions, the distribution over states evolves by pushing households through their choices and then through the shocks,

$$\Phi(j{+}1,\mathcal{S}') \;=\; \int_{\mathcal{S}} \phi\big(j,h(j,s),d,m\big)\, \Gamma\big(\mathcal{S}' \mid s,\, h(j,s), v(j,s), \tau(j,s), a'(j,s)\big)\, \mathrm{d}\Phi(j,s), \tag{28}$$

for $j = 1,\ldots,J-1$ and every measurable set $\mathcal{S}'$ of the state space $\mathcal{S}$ of (9), with the integral over the state s of the households of age j, together with the inflow of entrants

$$\Phi(1,\mathcal{S}') \;=\; \frac{\sum_{j\leq J_K} \int_{\mathcal{S}} \chi(j)\, \mathcal{N}\big(\mathcal{S}' \mid s\big)\, \mathrm{d}\Phi(j,s)}{\sum_{j\leq J_K} \int_{\mathcal{S}} \chi(j)\, \mathrm{d}\Phi(j,s)}, \tag{29}$$

where the integrals are again over s, $\mathcal{N}$ places the child according to (22) and $\chi(j)$ is the weight defined in Section 4.10. An entrant starts with the endowment T_0, is employed, has never had the disorder, holds no voucher, and carries SMI with the prevalence observed at age 26.[25]

[24] The suppliers are outside the economy: what they earn along the supply curve is counted neither in welfare nor in the budget.

[25] A disorder acquired before that age is therefore acquired in the model only after entry; however, the share of adults with a SUD still matches the data (Section 5).

4.14 Competitive equilibrium

A competitive equilibrium is a collection of

- value functions $\left\{\{V_t(j,\cdot)\}_{j=1}^{J}\right\}_{t=0}^{\infty}$;
- policy functions $\left\{\{h_t(j,\cdot),\, v_t(j,\cdot),\, \tau_t(j,\cdot),\, a'_t(j,\cdot)\}_{j=1}^{J}\right\}_{t=0}^{\infty}$;
- distributions $\left\{\{\Phi_t(j,\cdot)\}_{j=1}^{J}\right\}_{t=0}^{\infty}$; and
- prices, policies and aggregates $\left\{p_{vt},\, \pi_{Vt}\right\}_{t=0}^{\infty}$, together with $\bar{y}$, y^{med} and FMR, which carry no date because they are kept fixed at their benchmark values,

such that, at every date t,

1. the policy functions solve (24) given its terminal condition, and $\{V_t(j,\cdot)\}_{j=1}^{J}$ are the associated values;
2. $\Phi_{t+1}(j{+}1,\cdot)$ follows from $\Phi_t(j,\cdot)$ by the law of motion (28) together with the entrants of (29) and (22);
3. the government budget (26) holds at π_{Vt} with $\mathcal{R} = \bar{\mathcal{R}}$;
4. the drug market clears at p_{vt}, so (27) holds.

A stationary equilibrium is a special case in which all objects are constant. I calibrate the model in a stationary equilibrium, and the long-run policy comparisons also report stationary equilibria. When I hold π_V or the drug price at their benchmark values in any experiment, I exclude the budget condition or the drug-market condition, respectively.

5 Calibrating the quantitative model

The model has fifty-nine parameters, some of which vary by age. Thirty-eight are calibrated externally, from data or the literature, and twenty-one internally. The twenty-six that carry this paper's story are in Table 3, with the moment, source, data and model value behind each, and are discussed below in numbered blocks of parameters that work through similar mechanisms. The other thirty-three, common to most life-cycle models, are in Appendix A to save the reader time; its blocks continue the numbering. Three further parameters govern drug testing and exclusion from the voucher; they play no role in the benchmark and are set with the experiment in Section 6. `data/DATA_APPENDIX.md` in the replication package documents the dataset, year, universe and computation behind every estimate, and the package carries all datasets, so nothing has to be downloaded.

5.1 The twenty-six parameters that carry the story of this paper

Block 1: Who uses drugs. The five parameters in this block decide the share of participants and who participates. They decide how much there is for a policy to affect.

θ, the weight on drugs in utility. The weight in utility given to drugs mostly determines what share of its budget a household that uses drugs spends on drugs. To a lesser extent, a higher weight also makes using at all more attractive. As it rises, use therefore rises on both the extensive and the intensive margin, and with it the externalities and what either policy has to act on. It is calibrated internally, at 0.17, to aggregate drug spending by users over their aggregate income, 16.0 percent, from retail drug spending in Midgette et al. (2019) and, in NSDUH 2024, the incomes of adults aged 26 and over who use drugs.

b, the marginal utility from the first unit of drugs. The marginal value of the first unit of drugs goes as θ/b, so a larger b makes the first units worth less and a household with little to spend buys none. As b falls, the marginal utility from the first unit rises, and so do overall drug use and the externalities that policy can affect. It targets a participation rate of 8.90 percent, the NSDUH 2024 rate of a drug use disorder of any severity among adults aged 26 and over.[26]

[26] A user in the model is therefore a household whose use of any illicit drug, marijuana among them, amounts to a disorder, mild included. A household with a SUD is one whose disorder is moderate or severe (next item). Use that never reaches a disorder is not modelled.

Table 3: The twenty-six parameters that carry the story of this paper

Parameter	Description	Set	Moment and source	Data	Model	Value
Block 1: Who uses drugs						
θ	Weight on drugs in utility	Int.	Drug spending over income, Midgette et al. (2019)	16.0%	14.8%	0.165
b	Marginal utility from the first unit of drugs	Int.	Any drug use disorder, NSDUH 2024	8.90%	8.96%	0.0054
π_d	Chance that a year of use leads to a SUD	Int.	Share of users with a SUD, NSDUH 2024	41.3%	42.6%	0.0345
$\kappa_{\phi d}$	Increased mortality with a SUD	Int.	Income of drug users over average, NSDUH 2024	74%	62%	4.00
$\aleph$	Flow value of being alive	Int.	VSL, Viscusi and Aldy (2003)	80	81	87.6
Block 2: Costs of homelessness and vouchers						
κ_d^{ue}	How much less likely it is to regain employment with a SUD	Int.	SUD share of the homeless, Gutwinski et al. (2021)	21.7%	20.2%	3.78
h_1	Service flow of homelessness	Int.	Homelessness band, HUD PiT 2023 and Burt et al. (2001)	0.40–1.00%	0.62%	0.0216
$\kappa_{\phi H}$	Mortality when homeless	Ext.	Meyer et al. (2023)	1.60	n.a.	1.60
κ_H	Employment penalty of homelessness	Ext.	Desmond and Gershenson (2016)	0.20	n.a.	0.20
$\underline{c}$	Food stamp maximum allotment	Int.	SNAP outlays over output	0.42%	0.43%	0.0879
π_V	Chance of drawing a voucher	Int.	Recipients over eligible, HUD 2023	26.6%	27.5%	0.0675
T_0	Endowment at entry to adulthood ($j = 1$)	Int.	Share of homeless aged 25 to 34, HUD PiT 2024	26.0%	26.4%	0.111
Block 3: SMI chain						
ι	SUD multiplier on SMI onset	Ext.	Danish registers, Nielsen et al. (2017)	2.00	n.a.	2.00
λ_m	Annual chance of recovering from SMI	Ext.	SMI ten-year recovery rate, Åsbø et al. (2022)	50%	n.a.	0.066
ω_m	Level of the SMI onset profile	Int.	SMI share of the population, NSDUH 2024	4.82%	4.83%	0.0037
κ_m^{ue}	How much less likely it is to regain employment with SMI	Int.	SMI share of the homeless, Gutwinski et al. (2021)	25%	24.7%	7.71
μ_m	SUD recovery multiplier for SMI	Ext.	Dual-diagnosis relapse, Bradizza et al. (2006)	0.82	n.a.	0.82
$\kappa_{\phi m}$	Mortality multiplier for SMI	Ext.	Olfson et al. (2015)	2.50	n.a.	2.50
Block 4: Recovery and treatment						
$\bar{\pi}_r$	Baseline SUD recovery rate	Ext.	SUD ten-year remission rate, Vaillant (1995)	22%	n.a.	0.025
μ_H	SUD recovery when homeless	Int.	Abstinence, housed/homeless, Milby et al. (2005)	1.47	1.45	0.696
g	Treatment effect on recovery	Ext.	Remission on buprenorphine, Paul et al. (2024)	2.00	n.a.	2.00
$\bar{\tau}^u$	Utility cost of treatment	Int.	Treatment take-up, NSDUH 2024	24.5%	24.9%	4.49
c_{treat}	Public cost of a year of treatment	Ext.	Residential treatment episode, Roebuck et al. (2003)	$9,426	n.a.	0.133
Block 5: Externalities						
ω_c	Parent's weight on its child	Int.	Two-adult over lone-parent households' use, less one, NSDUH 2024	17.5%	17.7%	0.085
δ_d	Earnings the child loses because of a parent's SUD	Ext.	Earnings lost in utero, Nilsson (2017)	0.24	n.a.	0.24
Block 6: Drug market						
ε_s	Price elasticity of drug supply	Ext.	Mace et al. (2020)	1.46	n.a.	1.46

Notes: the Model column is the Housing First benchmark. I use the notation n.a. in the Model column for externally calibrated parameters because in that case the model has no moment to compare to the data.

π_d, the chance that a year of use leads to a SUD. By governing how likely drug use is to become a disorder, this parameter determines how risky drug use is. When it rises, the externalities and moral hazard grow. It targets the share of users who have a SUD, 41.3 percent among adults aged 26 and over in NSDUH 2024.

$\kappa_{\phi d}$, increased mortality with a SUD. $\kappa_{\phi d}$ sets how much a SUD raises the chance of dying, and mortality truncates a user's value of life. Because this is an uninsurable risk, a rise in $\kappa_{\phi d}$ hits the households with the highest values of life hardest, which reverses the income gradient; as the stylized model of Section 3 shows, this makes it a key parameter. It is calibrated internally, at 4.00, to the income of users relative to the average, a value within the range of the mortality rate ratios of a SUD in the literature: 3.91 in the Danish registers (Plana-Ripoll et al., 2019) and 6.6 among Norwegians in specialist care for a SUD (Heiberg et al., 2018). Users earn 62 percent of the average in the model against 74 percent in the data.

$\aleph$, the flow value of being alive. While $\kappa_{\phi d}$ sets how much a SUD raises the chance of dying, $\aleph$ decides the value of life. As it rises, dying costs more and use falls. It targets a VSL of 80 times average labour income (Viscusi and Aldy, 2003).[27]

Block 2: Costs of homelessness and vouchers. Both policies work on this block, from opposite ends: each parameter says how welfare reducing a state is, and so what a voucher and its removal are worth in it.

κ_d^{ue}, how much less likely it is to regain employment with a SUD. An unemployed household with a SUD finds work at the rate $\bar{\pi}^{ue}$ divided by $\kappa_d^{ue} > 1$. As κ_d^{ue} rises, the expected unemployment spells of households with a SUD lengthen and they are likelier to lose their housing: this is the link from the disorder to the street, and it shapes how much Treatment First deters. It is calibrated internally to the SUD share of the homeless, 21.7 percent in Gutwinski et al. (2021).

h_1, the service flow of homelessness. This parameter sets how welfare reducing the outside option is,

[27] No household has a negative value of life in equilibrium, so death is never optimal. Because the value of being alive enters utility additively and utility is concave, the VSL rises faster than consumption, roughly with its square at the model's risk aversion, as in Hall and Jones (2007). Estimates of the income elasticity of the VSL are lower across people at a point in time, 0.5 to 0.6 in Viscusi and Aldy (2003), than over time, 1.5 to 1.7 in Costa and Kahn (2004).

which affects the value of life: a household with little to lose from dying faces a smaller mortality cost of using. As h_1 rises, a shelter is less welfare reducing, a voucher is worth less and Treatment First has less to act on. It targets a homelessness rate within 0.40 to 1.00 percent of households: the floor is HUD's 2023 PiT count, which counts a single night; the ceiling is the share homeless at some point over a year, from Burt et al. (2001). Its value is 53 percent of the smallest rental (Appendix A), and the model delivers an aggregate homelessness rate of 0.62 percent.

$\kappa_{\phi H}$**, mortality when homeless.** This parameter sets how much more likely a homeless household is to die. As it rises, the cost of homelessness rises, a voucher is worth more and Treatment First's deterrence is stronger. It is set externally to multiply baseline mortality by 1.60 at every age, the mortality ratio for homeless adults against poor housed adults in Meyer et al. (2023).

κ_H**, the employment penalty of homelessness.** This parameter sets how much likelier a household in a shelter is to lose its job and how much less likely it is to find one: separations are $1 + \kappa_H$ times as frequent and job finding $1 - \kappa_H$ times as fast. Housing First recovers that employment directly, whereas Treatment First does so only as the fall in SUD lowers unemployment and homelessness over time. As κ_H rises, homelessness costs more, and both policies have more to act on. It is set externally at 0.20, from Desmond and Gershenson (2016).

$\underline{c}$**, the food stamp maximum allotment.** This parameter sets how low consumption can go for the poorest households, with no income, assets or voucher, and so where utility is bounded from below. As it rises, the value of being alive rises, mortality costs more and Treatment First has more to deter. It is calibrated internally to food stamp spending over output, 0.42 percent: outlays from the United States Department of Agriculture (USDA) over GDP.

π_V**, the chance of drawing a voucher.** This is the policy dial itself, and it holds the whole trade-off. Raising it houses more households, which reduces the *childhood homelessness externality*, and makes life worth more, which makes Treatment First's deterrence more effective. In the benchmark it is calibrated internally, at 0.068, so that the share of income-eligible households who hold a voucher is aligned with the 26.6 percent in HUD's Picture of Subsidized Households, 2023.

T_0**, the endowment at entry to adulthood (**$j = 1$**).** A child who becomes an adult starts adult life with T_0 times average earnings, which sets how likely a young adult is to end up in a shelter in its first years. It captures, in a reduced form, the financial help that young adults receive from their parents, such as inter vivos transfers, gifts or help with housing, which cannot be observed directly in the data. As it rises, fewer parents are homeless, and Treatment First has less of an effect on drug use during parenthood, and thus less of an effect on children. Its moment is the share of the homeless aged 25 to 34, 26.0 percent in HUD's 2024 PiT count.

Block 3: SMI chain. This block determines how much Treatment First prevents beyond drug use and SUD. This is because a SUD raises the chance of SMI, and SMI lowers employment and raises mortality.

ι**, the SUD multiplier on SMI onset.** This is the key parameter of this block because it determines how much a SUD affects the onset of SMI. As it rises, a SUD increases the prevalence of SMI more, and Treatment First reaches further, because preventing the disorder then also lowers overall SMI. It is set externally at 2.00, between the hazard ratio of 1.34 for any SUD that Hjorthøj et al. (2018) estimate for the conversion from schizotypal disorder to schizophrenia and the 6.04 for any substance abuse that Nielsen et al. (2017) estimate for the onset of schizophrenia, both in the Danish registers.

λ_m**, the annual chance of recovering from SMI.** This parameter determines how long an SMI spell is expected to last. As it rises, SMI becomes less persistent and Treatment First's deterrence of drug use declines, because the SMI spells a SUD can trigger are shorter on average. I set it externally to 0.066, which is an annual hazard consistent with the ten-year recovery rate of 50 percent for bipolar disorder in Åsbø et al. (2022).

ω_m**, the level of the SMI onset profile.** This parameter scales the probability of developing SMI at every age. As it rises, a SUD has a larger effect on SMI, and Treatment First reaches further than just drug use and SUD. It is calibrated internally to the share of the population with SMI, 4.82 percent, the prevalence in NSDUH 2024.

κ_m^{ue}**, how much less likely it is to regain employment with SMI.** The same as κ_d^{ue} for SMI: a household with SMI finds work at the rate $\bar{\pi}^{ue}$ divided by $\kappa_m^{ue} > 1$. As it rises, expected unemployment spells with SMI lengthen and SMI costs more. Its moment is the SMI share of the homeless, 25 percent in Gutwinski et al. (2021), since a household out of work longer is likelier to become homeless.

μ_m**, the SUD recovery multiplier for SMI.** The chain's second direction: a SUD raises the chance of SMI, and SMI makes a SUD more persistent. As it falls, recovering from a SUD is less likely, and Treatment First has more to overcome. It is set externally at 0.82 from the dual-diagnosis relapse rates in Bradizza et al. (2006).

$\kappa_{\phi m}$**, the mortality multiplier for SMI.** The chain's last link, through which SMI shortens life. As it rises, more households with SMI die, and Treatment First has more to work on, because less drug use means less SUD, less SMI and fewer deaths. It is set externally at 2.50, the middle of the standardised mortality ratios for SMI in Olfson et al. (2015).

Block 4: Recovery and treatment. Both policies work through this block: Treatment First encourages seeking treatment, and Housing First buys recovery by housing people, since recovery is likelier while housed. The first two parameters determine how quickly recovery happens, the next two decide how much treatment raises recovery and how likely a household with a SUD is to go to treatment, and the last parameter determines how much it costs the government to send a household to treatment for a SUD.

$\bar{\pi}_r$**, the baseline SUD recovery rate.** This parameter is the annual chance that a housed household recovers from a SUD, the level everything else in the block scales. As it rises, disorders are expected to end more quickly on their own, and there is less for either policy to do. It is set externally at 0.025, the annual hazard implied by the ten-year remission rate in Vaillant (1995).

μ_H**, SUD recovery when homeless.** This parameter sets how much less likely recovery is in a shelter, and so how much recovery a voucher buys beyond shelter. As it falls, housing buys more recovery and Housing First is more effective in curing a SUD; near one, Housing First has little effect. It targets the effect of housing on recovery in Milby et al. (2005), who find that housing improves recovery chances by 47.3 percent.

g**, the treatment effect on recovery.** The instrument through which Treatment First reaches households that already have a SUD, which matters most in the short run. As it rises, treatment is likelier to end a SUD, and Treatment First has a larger margin to act on. It is set externally at 2.00, which is how much medication for opioid use disorder raises remission: rates near double those without it (Paul et al., 2024), and randomised trials of agonist medication against placebo find at least as large an effect on abstinence (Fudala et al., 2003).

$\bar{\tau}^u$**, the utility cost of treatment.** Take-up is a choice, and this utility cost is what makes households decline a treatment that would raise their chance of recovering. As it rises, fewer take treatment up, and Treatment First induces fewer households with a SUD to seek it. It is calibrated internally to treatment take-up: 24.5 percent of adults with a SUD received substance use treatment in the past year in NSDUH 2024.

$c_{\mathbf{treat}}$**, the public cost of a year of treatment.** This parameter is what the government pays for each household with a SUD that takes up treatment, under both policies. It ties treatment to the government's budget. Treatment First raises take-up, since entering treatment and stopping is how a household with a SUD keeps its voucher, so part of what the screen saves goes on treatment rather than on vouchers for others. As c_{treat} rises, Treatment First frees less for vouchers and π_V rises less. It is set externally to \$9,426 a year, 8.4 percent of average earnings, the cost of a residential treatment episode in Roebuck et al. (2003).

Block 5: Externalities. These two parameters decide what is an externality and how large it is.

ω_c**, the parent's weight on its child.** A parent bears the share ω_c of what its choices cost its child, in childhood and through the productivity penalty. As it rises, the parent counts more of the child's loss, so the *budget, earnings and childhood homelessness externalities* left for either policy to correct are smaller. It is identified by a counterfactual moment: drug use when the child is given no weight, against

drug use at ω_c, with every other parameter unchanged.[28] The data moment holds the household fixed as well. In NSDUH 2024, an unmarried adult living with one other adult and no child was 17.5 percent more likely to have used illicit drugs in the past year than a lone parent living with one child. The lone parents are reweighted to the other group's age, sex, marital status (never married, divorced or separated, or widowed) and family income; with two members in each household, equal family income is equal income per person.[29]

δ_d**, earnings the child loses because of a parent's SUD.** The child inherits not the disorder but a worse productivity draw, which makes it likelier to be poor, to use, to acquire a SUD and SMI, to be homeless and to die earlier. As it rises, with $\omega_c < 1$, the *earnings externality* grows, which favours whichever policy prevents more drug use: Treatment First by deterring the parent, Housing First by making recovery likelier once housed. It is set externally at 0.24, the earnings loss, at age 32, that Nilsson (2017) measures for children of mothers under 21 exposed in utero to a Swedish alcohol experiment. Section 2 explains why the value is conservative. No study measures the earnings cost of a parent's disorder after birth directly; Nilsson's is the closest causal estimate, and the SUD odds ratio of Block 6 of the validation (Section 5.2) is the indirect check on its size.[30]

Block 6: Drug market. One parameter makes the drug price endogenous, so that it moves with demand.

ε_s**, the price elasticity of drug supply.** This parameter determines the general-equilibrium drug-price effect that works against Treatment First. Treatment First deters users and lowers drug demand and thus the drug price. However, a cheaper drug pulls other households into using. As this parameter's value rises, the drug supply becomes more elastic and the drug price drops less when demand decreases, which means that the offsetting effect is smaller. I set it to 1.46, which is the estimate in Mace et al. (2020) for the supply elasticity of cannabis, using Washington State administrative data.[31]

5.2 Validation

Table 4 compares the model with moments it was not fitted to, in numbered blocks, and each block says why it matters for the experiments.

Block 1: Homelessness. The first row gives each age band's share of the homeless; the youngest band is the target of T_0 and the other four are free. The model puts 37.9 percent of the homeless at ages 35 to 44, against 27.2 in HUD's PiT count, and 11.5 percent at 55 and over, against 25.9. Of the homeless in the model, 21.4 percent are employed, against 46 in the data, and their income is 6.5 percent of the average, against 19.1 in Meyer et al. (2024). Most of the homeless in the model are therefore poor and in the age range of parenthood, which aligns with the data. As a result, Treatment First's direct effects fall harder on households with children.

Block 2: Who uses and who has a SUD. Users in the model are somewhat younger than in the data: 67 percent of them are 26 to 34, against 45 in NSDUH 2023, and their mean age is 34.6, against 39.6.

[28] With $\omega_c = 0.69$, the weight on children that Nishiyama (2000) estimates and the upper end of the literature, and with b re-matched to drug use, Treatment First still raises a newborn's welfare, by 3.18 percent of lifetime consumption, against 2.57 in the benchmark. Less of that gain is an externality, however: 23 percent of it, against 76 percent in the benchmark (the last column of Table 6), because a parent with this weight counts most of what its choices cost its child, 1.64 percent of lifetime consumption against 0.19. Quantitative models in the dynastic tradition of Barro and Becker (1989) typically use lower weights (Lee and Seshadri, 2019; Abbott et al., 2019).

[29] This moment counts any past-year use of an illicit drug, a broader measure than the model's, because too few lone parents in the sample have a disorder for the comparison to give a statistically reliable measure. It is therefore used only for how much use responds, in proportion, and not for its level: the model matches it as the proportional rise in its own users.

[30] The earnings externality is only 18 percent of the welfare gain from Treatment First (Section 6.3), so the ranking of the two policies does not rest on the penalty's size.

[31] I am not aware of any direct estimate for an illicit drug. Cannabis is the closest market I was able to find. While not identical, it is still a Schedule I substance at the federal level, which means that its suppliers operate under federal prohibition, much like an illicit drug supplier does. Mace et al. estimate a short-run elasticity over a month. Larger windows of time, such as two and three months, produce higher elasticities. The long-run elasticity of an illicit supply is likely higher, and studies of illicit drugs take it to be infinite (Becker et al., 2006).

Unemployment among households with a SUD is 14.5 percent, against 16.2 in the data. Households with SMI are 2.64 times more likely than others to use drugs, against 2.44, and excess deaths due to SUD account for 14.5 percent of deaths at ages 25 to 44, against 20.0 percent from drug poisonings in the Centers for Disease Control and Prevention (CDC) WONDER database.

The calibration targets only the average income of users, but the model is able to generate a distribution of drug use by income in line with the data. Figure 2 shows the share of households that use drugs at each level of income relative to the mean. As in the data, use is highest at the bottom of the income distribution and lowest at the top: 18.3 percent of households with less than 0.22 of the mean income use drugs, against 13.7 percent in NSDUH 2024, and 4.2 percent of those with more than 1.62 times the mean, against 4.8 percent. Between 0.43 and 1.62 times the mean, use in the model is flatter and lower than in the data, 5.9 to 6.3 percent against 7.2 to 10.2. Both differences lower the average income of users in the model, which is why it falls slightly short of its target in Table 3.

The age of users and their income both matter for the experiments. Both policies reach a child through its parent's decisions, so the age of users decides how many children their use touches. Furthermore, since the vouchers are means-tested, the lower in the income distribution users sit, the more of them are eligible for a voucher, and the more of them, and of their children, Treatment First's screen reaches. Lastly, since households with SMI use drugs and are homeless at higher rates than the rest, as in the data, the model also captures that Treatment First's screen falls disproportionately on them: they are the likeliest to fail it.

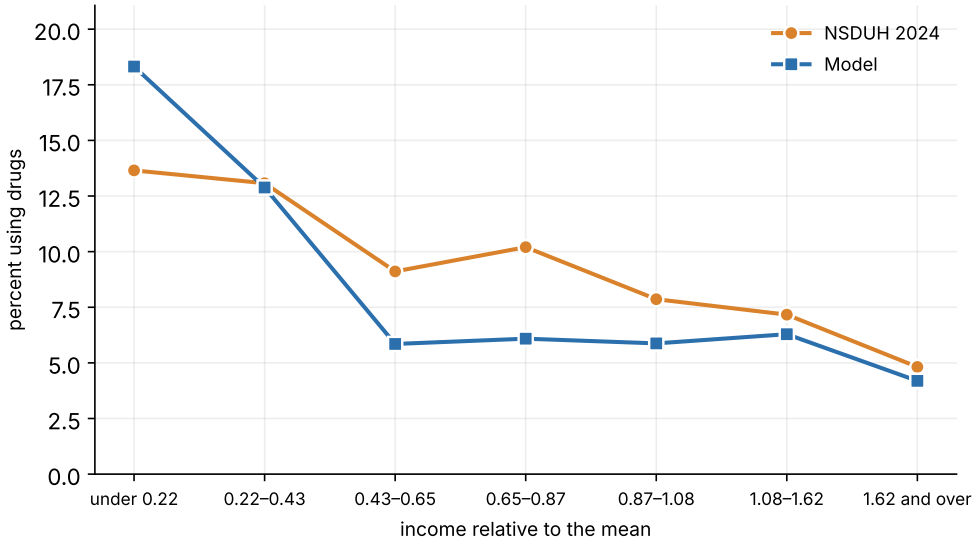

Figure 2: Drug use by income relative to the mean, model and data

Notes: in NSDUH 2024, the share of adults aged 26 and over with a drug use disorder of any severity, by band of total personal income relative to the mean of the band midpoints (90,000 dollars for the open top band); in the model, the share of households that use drugs in the Housing First benchmark, in the same bands of total income relative to the mean.

Block 3: Housing and vouchers. In the model, 58.7 percent of housed households spend over thirty percent of their income on rent, against 43.2 percent of renters in the SCF. A voucher holder pays 39.0 percent of its income in rent,[32] against 31.2 in HUD's Picture of Subsidized Households, and 39.2 percent of voucher holders live mainly on wages, against 28.0; the others are mostly retired or unemployed. Housing takes a large share of poor households' income, so the consumption Treatment First puts at stake when it conditions the voucher is of a similar size in the model and in the data.

[32]The rule says that the tenant pays thirty percent of its income on rent, but only when it spends no more than the fair market rent. Therefore, a holder that rents for more than the fair market rent pays the difference itself. This is why the share of income paid by voucher holders is above thirty percent.

Block 4: Income and wealth distributions. The lowest-income fifth of households receives 3.40 percent of income in the model, against 2.71 in the SCF, and holds 0.27 percent of net worth, against −0.23; the bottom half holds 6.3 percent, against 2.2. Both policies act on the households that receive vouchers, the poorest, and the model captures their relative poverty broadly in line with the data.

Block 5: Drug price elasticities. The calibration targets neither the participation nor the intensive elasticity of drug demand. The model's participation elasticity is −1.32, somewhat larger in absolute value than the estimates of about −0.3 to −0.9 in Saffer and Chaloupka (1999) and Grossman and Chaloupka (1998), and its intensive elasticity, over all users, is −0.63, in the middle of the estimates of about −0.3 to −0.8 in Grossman and Chaloupka (1998) and Olmstead et al. (2015). These elasticities are the response of drug use to its price, which is separate from the response to Treatment First itself. The latter, with the drug price held fixed, is matched to the evidence on impact when the detection rate is calibrated (Section 6). Given that, a larger price response can only work against Treatment First: as Treatment First lowers the drug price, more households return to using, and the more elastic participation is, the more of them do. A welfare gain from Treatment First is therefore conservative in this respect.

Block 6: Transmission. A parent's SUD and homelessness also carry over into its child's adult life, in the model as in the data. A child of a parent with a SUD has 1.46 times the odds of acquiring one in the model, within the range of 1.44 to 2.51 in Mellentin et al. (2016) and Yoon et al. (2013). A homeless adult has 6.23 times the odds of being the child of someone who was homeless as well, above the 1.8 to 2.4 odds ratios estimated in Bassuk et al. (1997).

Transmission in the model is therefore at the low end of the evidence on the SUD, the margin Treatment First acts on, and above it on homelessness, the margin Housing First acts on. With the penalty switched off, in the economy without the externalities of Section 6.2, the SUD odds ratio is 1.02, so the transmission runs through δ_d. The value of δ_d that would put the model in the middle of the range is above 0.24, so the calibrated value is likely at the low end of what the evidence supports. The model loads the externality on children towards Housing First more than Treatment First, so if Treatment First still raises welfare in the experiments below, that result is conservative.

Furthermore, in the model, 5.82 percent of children live with a parent who has a SUD; in NSDUH 2024, 4.6 percent of children whose parents are aged 26 or older live with a parent who has a moderate or severe drug use disorder. The externalities on the child in the model therefore reach a share of children similar to that in the data.

Block 7: Losing a voucher. Enrolling in Housing First was estimated to lower the three-year mortality of homeless veterans with mental illness by 4.6 percentage points (Costantini, 2025). In the model, with the drug price and π_V held, I compare households with SMI whom Treatment First's revocation puts on the street with the same households had they kept their voucher: losing it raises three-year mortality by about 3.6 percentage points, the same order of magnitude. For the experiments, this matters because in the model, the effect of losing a voucher on the survival rates of households losing it is of a similar magnitude to the one measured by Costantini.

Block 8: Treatment under a condition. Milby et al. (2005) randomised abstinence-contingent housing against housing without conditioning, among homeless adults with a cocaine disorder in treatment: the contingent arm reached 8.32 consecutive weeks of abstinence against 6.60, a ratio of 1.26. The model's counterpart is the recovery hazard of voucher holders, whose voucher is conditional under Treatment First, against housed households without a voucher, both with a SUD: 1.40 times in the first year of the condition, the horizon of Milby's trial, close to its ratio. This is directly relevant for the experiments because Treatment First reaches households with a SUD through treatment, and the relevant households in the model respond about as strongly as the participants did in the trial over a similar horizon.

Table 4: Untargeted moments

Moment	Data	Model	Source
Block 1: Homelessness			
Share of homeless by age, 25–34 to 65+[a]	26.0, 27.2, 21.0, 18.4, 7.5	26.4, 37.9, 24.2, 10.7, 0.8	HUD PiT 2024
Employed share of the homeless	46	21.4	Meyer et al. (2024)
Income of the homeless, over average	19.1	6.5	Meyer et al. (2024)
Block 2: Who uses and who has a SUD			
Share of users by age, 26–34 to 65+	45, 19, 14, 12, 10	67, 16, 10, 5, 2	NSDUH 2023
Mean age of users, years	39.6	34.6	NSDUH 2023
Unemployment given a SUD	16.2	14.5	NSDUH 2024
Drug use with SMI over without, ratio	2.44	2.64	NSDUH 2024
Drug deaths as a share of deaths, 25–44	20.0	14.5	CDC WONDER
Block 3: Housing and vouchers			
Renters paying over 30% of income	43.2	58.7	SCF 2022
Rent over income, voucher holders	31.2	39.0	HUD PSH 2023
Voucher holders living on wages	28.0	39.2	HUD PSH 2023
Block 4: Income and wealth distributions, shares of the total			
Income, bottom 1, 5, 10, 20%	0.01, 0.31, 0.92, 2.71	0.01, 0.19, 1.00, 3.40	SCF 2022
Net worth, bottom 1, 5, 10, 20, 50%	−0.16, −0.28, −0.29, −0.23, 2.2	0.00, 0.00, 0.00, 0.27, 6.3	SCF 2022
Block 5: Drug price elasticities			
Participation (extensive margin)	−0.3 to −0.9	−1.32	Saffer and Chaloupka (1999), Grossman and Chaloupka (1998)
Intensive margin (users)	−0.3 to −0.8	−0.63	Grossman and Chaloupka (1998), Olmstead et al. (2015)
Block 6: Transmission			
Child of a SUD parent acquires a SUD, odds ratio	1.44, 2.51	1.46	Mellentin et al. (2016), Yoon et al. (2013)
Homeless adult had a homeless parent, odds ratio	1.8 to 2.4	6.23	Bassuk et al. (1997)
Children living with a parent with a SUD, %	4.6	5.8	NSDUH 2024
Block 7: Losing a voucher			
Three-year mortality, households with SMI put on the street, pp[b]	4.6	3.6	Costantini (2025)
Block 8: Treatment under a condition			
Abstinence, contingent over unconditional housing, ratio[c]	1.26	1.40	Milby et al. (2005)

Notes: percent, except the elasticities and the odds ratios of the transmission block, the ratio in Block 8, the mean age (years) and the SMI ratio in Block 2, and percentage points in Block 7; the model is the Housing First benchmark, except in Blocks 7 and 8, which apply Treatment First to it (notes b and c). [a]The share aged 25 to 34 is the target of T_0 in Table 3, so of this row only the other four bands are untargeted. [b]Data: Costantini's instrumental-variables estimate of how much enrolling in the Housing First programme of the Department of Veterans Affairs lowers the three-year mortality of homeless veterans with mental illness. Model: the three-year mortality gap between the households with SMI whom Treatment First's revocation forces into homelessness and the same households had they kept their voucher, with the drug price and π_V held. [c]Data: consecutive weeks of abstinence in the arm housed on condition of abstinence over the arm housed without it, homeless adults with a cocaine disorder in day treatment. Model: the recovery hazard of voucher holders with a SUD over that of housed households with a SUD and no voucher, in the first year of Treatment First.

6 Experiments and results

Every experiment replaces Housing First, the benchmark, with Treatment First, the rule of Section 4.9, and keeps the programme rationed and the tax system as it is in the benchmark. Within each of my experiments, I play around with two objects. The first object is the drug price: I either hold it fixed or allow it to clear the drug market. The second is the probability of drawing a voucher, π_V: I either hold it at its benchmark level or let it adjust to maintain a balanced budget. Within each of my experiments, I switch these clearing conditions on and off, and across my experiments, I also turn the externalities on the children on and off. Overall, I conduct three experiments. The first two compare steady states (Section 6.2), each in its own half of Table 5, and the third considers the transition (Section 6.4).

The first experiment asks whether moral hazard alone justifies conditionality. The exact definition of moral hazard is as follows. It is the impact that insurance has on the behaviour of the insured when deciding whether to avoid risk. When the cost of the loss is borne by others, the insured is less likely to take measures to avoid it, and thus the bad state of the world is more likely to materialise (Arrow, 1963; Pauly, 1968). The connection to Housing First is direct. Housing First insures a household against losing its home when drug use leads to a SUD, unemployment and homelessness. Therefore, part of the cost of using falls on the government's budget, which means that others have to pay for it. This is the case critics of Housing First normally make.

To test whether moral hazard justifies Treatment First, I remove the children from welfare and from the parent's preferences, and make their productivity independent of what the parent did. In that case, a household's drug use can only harm the household itself and the budget. Therefore, any gain Treatment First generates must be due to correcting moral hazard, rather than the externalities imposed on children. To do this, I first obtain the benchmark without externalities by solving the stationary equilibrium of the model under Housing First with these new configurations (with every calibrated parameter held fixed). I then introduce Treatment First in two separate runs, and in both I keep the drug price fixed at its benchmark level. In the first run, I also keep π_V at its benchmark level, which means that the screen is the only change.

Therefore, this run shows what deterring users does to the users themselves before the budget comes into play. In the second run, I allow π_V to balance the budget. This run captures the gain from correcting the cost of moral hazard to the budget, a common critique of Housing First. If Treatment First lowers welfare in both runs, the conclusion is then that moral hazard alone does not justify conditional housing assistance. For completeness, I also show the case in which the drug price clears together with π_V.

The second experiment introduces Treatment First in the full calibrated model, with the externalities on children, in three steps. In each step, I adjust one additional element, which isolates each effect. The first two steps repeat the two runs of the first experiment, which had no externalities. In the first, I keep the drug price and π_V fixed at their Housing First levels. Thus, again, only the screen acts, and the only difference between the first and second experiments is whether drug use harms children, which isolates the impact of the externalities. Section 6.3 then breaks down the contributions of each of the externalities within each of these runs. Second, π_V clears the budget, as in the first experiment's second run, so that the screen's savings are spent on vouchers for others. This shows what that spending is worth once the children are counted, with its externality separated the same way. Third, the drug price clears the drug market as well. Allowing the drug price to adjust is the last change I make because this is a pure general-equilibrium price effect. When the price can drop and the screen lowers demand, Treatment First's effect is muted because the lower price entices some households to use drugs again. I refer to this as the main experiment because both the price and π_V adjust, as they would after a real reform, and thus it asks the ultimate question, which is whether Treatment First raises or lowers welfare in full general equilibrium. Table 5 also shows, for both experiments, the drug price clearing with π_V held.

The third experiment is the transition from Housing First to Treatment First in the full model, with both the drug price and π_V clearing the drug market and the budget, respectively, every period (Section 6.4). The two steady states are many periods apart. However, in the short run, most households that have a SUD do not recover and thus, when the reform takes effect, can only keep their assistance by entering treatment and stopping use. The transition takes these concerns into account and demonstrates what the early costs of the reform are, who bears them, and whether children born at the time of the reform gain as well.

After the main transition, I explore alternative transitions in which households with a SUD cannot stop using (Section 6.5): the screen with no exemption for treatment from the first day of the reform, the same screen announced five periods before it starts, and the same screen with treatment alone keeping the voucher for its first five periods, each at two detection rates. Section 6.1 defines the welfare criterion all three use.

The screen. The detection rate p_{det} is the annual chance that the government catches a user who has a voucher or who is offered one. This detection rate therefore determines how risky using is, and as a result, how strongly Treatment First deters use. As the detection rate rises, the government is more likely to catch users, and more users stop. I set it so that the screen deters use as much as a drug test with a severe penalty does in the closest evidence, the US military's random testing (Section 2). After the military began testing at random and dismissing those who failed, service members who stayed were 61 percent less likely to use marijuana in the past year than the non-treated group (Mehay and Pacula, 1999).[33]

In the model, the counterpart applies Treatment First to the household distribution, drug price and π_V from the Housing First benchmark. And it follows each user who faces the screen, whether they hold a voucher or are eligible and were offered one. With $p_{\text{det}} = 20$ percent, 62 percent of them stop when the screen is introduced,[34] and none starts.[35] A household that does not use, and is in treatment if it has the disorder, is never flagged.[36]

[33]The 61 percent figure is the raw comparison among members who stayed. Accounting for those who left, the decline in use was between 11 and 45 percent. At half the calibrated rate, 41 percent of the users subject to the screen stop, inside that range (footnote 35). At a quarter of the calibrated rate, 29 percent stop, inside the same range.

[34]The military figure is for any past-year use of marijuana, a broader measure than the model's, whose users have a disorder of any drug, marijuana among them. Therefore, the two are compared as proportional responses.

[35]At half the rate ($p_{\text{det}} = 10$ percent), 41 percent of the users subject to the screen stop on impact, about two thirds of the military's response. The results hold: in the long run, with the drug price and π_V clearing, Treatment First cuts drug use by 14 and homelessness by 6 percent, against 21 and 11 percent, respectively, at the calibrated rate, and a newborn is better off by 1.65 percent of lifetime consumption, against 2.57. At a quarter of the rate ($p_{\text{det}} = 5$ percent), 29 percent of the users subject to the screen stop on impact, inside the range that Mehay and Pacula find once those who left the military are counted. In the long run, Treatment First still cuts drug use by 9 and homelessness by 4 percent, and a newborn is better off by 1.01 percent.

[36]In practice, a false positive is nearly impossible: a drug test reports a positive only above a cutoff concentration, and a

The release rate ψ_x is set to 1/3, so that the expected exclusion is three years. That is the same period for which the Housing Choice Voucher programme already bars a household evicted from federally assisted housing for drug-related criminal activity (Code of Federal Regulations, Title 24, Section 982.553). The test cost c_{test} is set to 0.031 percent of average earnings in the economy, the equivalent of $35 a test. The Texas Legislative Budget Board's fiscal note for Senate Bill 11 puts a test at $35 (Legislative Budget Board, 2013), the upper end of the estimates, and taking the upper end again loads the experiment against Treatment First.

6.1 The welfare criterion

Every welfare number in this paper is a consumption-equivalent variation (CEV). For a newborn it is computed as follows. Write V^b for expected lifetime value under the benchmark and V^c for expected lifetime value under a counterfactual policy. Both lifetime values are measured at birth, under the veil of ignorance about every draw, including which household a child is born into. Each is taken under its policy's own distribution of newborns, which the policy moves, since a child's starting productivity depends on what happened to its parent.[37] The CEV Δ is the proportional change in non-housing and non-drug consumption, applied at every date and in every state, that makes a newborn under the benchmark as well off as the same newborn under the counterfactual:

$$V^b\big((1+\Delta)\,c\big) \;=\; V^c(c). \tag{30}$$

A positive Δ means the counterfactual generates an effect whose value, captured in terms of a change in permanent consumption, is positive, and a negative Δ means the opposite.

Whose welfare. I measure newborn welfare, which accounts for childhood and adulthood. For a child born in period t it is

$$W_t \;=\; \underbrace{\sum_{j=1}^{J_K} \beta^{\,j-1}\,(\xi(j)-1)\,\frac{\int_{\mathcal{S}} U\big(X_c(j,s)\big)\,\mathrm{d}\Phi_{t+j-1}(j,s)}{\Phi_{t+j-1}(j,\mathcal{S})}}_{C_t} \;+\; \underbrace{\beta^{J_K}\,\frac{\int_{\mathcal{S}} V_{t+J_K}(1,s)\,\mathrm{d}\Phi_{t+J_K}(1,s)}{\Phi_{t+J_K}(1,\mathcal{S})}}_{A_t}, \tag{31}$$

where $V_t(j,s)$ and $\Phi_t(j,s)$ are the value and the distribution of Section 4.10 and Section 4.13 in period t, the subscript being the date and j the age, and $X_c(j,s)$ is the bundle of (11) that a child shares with a parent of age j in state s. The state in both integrals is the parent's: a child at home has no state of its own, its bundle is its parent's, and the state it enters adult life with is drawn at J_K by $\mathcal{N}$.

The first term, C_t, is childhood. A household joins the workforce at $j = 1$ with its child just born, so the households of age j in period $t + j - 1$ are the surviving parents of the children born in period t, each child in its j-th year at home. The child's flow utility from the bundle it shares with its parent is averaged over the parents alive that year, weighted by $\xi(j) - 1$, the child's weight in the household's own equivalence scale, and discounted to the child's birth. Its parent counts the same flow at $\omega_c(\xi(j) - 1)$ in (24), so only ω_c separates the parent's valuation from the criterion's: the parent internalises the share ω_c of its child's childhood and leaves the share $1 - \omega_c$ external, as Section 4.10 defines it.[38]

The last term, A_t, is adult life, which begins at J_K: it is the average value at $j = 1$ of the households that enter in period $t + J_K$, placed by $\mathcal{N}$ as in (29), discounted by the J_K years spent at home. The parent's own welfare change, which Section 6.3 reports, is not discounted. This is because the parent views this welfare change from the perspective of age $j = 1$, whereas a newborn child reaches that age only J_K periods after they are born.

positive screen is then confirmed in a laboratory by a second, more specific test before it has any consequences.

[37] The ex-ante expected newborn welfare is the standard criterion in this literature (Conesa et al., 2009; Guvenen et al., 2023).

[38] A child whose parent dies before J_K stays in the average: for the rest of its childhood it is valued as the average child of its cohort rather than sent into adult life at the parent's death, as the law of motion (29) sends it, because an orphan has no consumption or dwelling of its own in the model. Sending it into adult life at the parent's death instead, with the probability $\chi(j)$ of (24), scores Treatment First lower: adult life carries the flow value of being alive ℵ and childhood does not, so that convention credits a child for losing its parent early, and Treatment First keeps more parents alive.

The externality enters welfare because childhood is counted at its own weight, $\xi(j)-1$, while the parent's weight on it is only $\omega_c(\xi(j)-1)$. Section 6.3 separates that externality from the rest of the gain. In a steady state the dates drop out.

I use two horizons for my welfare measure. The first one is the welfare of a newborn on the date the policy starts, who lives through the transition, and the second one is the welfare of a newborn born into the new long-run steady state.

6.2 The long run

Table 5 sets the long run under Treatment First beside the benchmark, and, in the first five columns, Housing First and Treatment First without the externalities.

Treatment First without externalities. To model the case without externalities, I consider the child to only appear as an adult. Its parent gives it zero weight, its productivity does not depend on whether its parent had a SUD or not, and its childhood is not counted in welfare. I keep every other parameter at its calibrated value, which means that these three changes are the only ones present in the comparison.

With the drug price and π_V held at their levels under Housing First, Treatment First cuts drug use by 28 percent and the share with a SUD by 27 percent, against Housing First with the externalities switched off, while homelessness falls by 5 percent (first two columns of Table 5). And yet, no household is better off under Treatment First, with newborns losing 1.17 percent of lifetime consumption as adults. These losses capture the value of the option removed from a rational, forward-looking agent.

Rebalancing the budget does not change the ranking. When π_V instead rebalances the budget at Housing First's drug price (third column), the screen's savings buy more vouchers. π_V therefore rises from 6.75 to 6.81 percent, and 58 percent of households gain, but only by 0.05 percent of consumption on average. The gain is small and spread thin, while the loss is concentrated on the users the screen takes out: 96 percent of households with a SUD are worse off, and newborns still lose 1.09 percent of lifetime consumption as adults (since childhood is not counted here). Correcting moral hazard's cost to the budget is still not enough to outweigh the loss of that option to households that choose optimally.

When the drug price is also allowed to clear the drug market (fifth column), newborns still lose 0.74 percent as adults. The change from the third column is the general-equilibrium effect of the drug price and not a correction of moral hazard: the screen lowers demand, the price falls by 4 percent, the cheaper drug draws users back, and more of them are caught and lose their vouchers, which the budget then gives to others.

Treatment First with externalities. Having ruled out moral hazard as a reason for sobriety conditions, I now test, in the three steps set out at the start of Section 6, whether the externalities are a reason to impose them. Each step is a column of Table 5. Here I follow what each step does to drug use, to homelessness and to the children, and give its welfare gain; Section 6.3 then takes each gain apart into the externality and the rest.

With the drug price and π_V both held at their Housing First levels (seventh column of Table 5), only the screen acts, as in the second column: drug use falls by 43 percent, homelessness falls by 8 percent, and the share of children in a shelter falls from 1.03 to 0.95 percent. In this partial equilibrium, the parents themselves lose, as they do without the externalities: the screen takes an option from them and gives nothing back, and they lose 1.19 percent of their own lifetime consumption, close to the 1.17 percent of the second column. But in contrast to the model without the externalities, a newborn gains 2.82 percent, because the child gains more than its parent loses. The children of the users the screen deters get more of their parents' consumption and housing, and more of them start adult life without the earnings penalty, while the parent counts only the share ω_c of either. In the aggregate, these *budget and earnings externalities*, which Housing First leaves in place, come with no trade-off against the *childhood homelessness externality*: by cutting use, the screen keeps more children out of a shelter than it sends to one by putting their parents out.

Letting π_V clear the budget at Housing First's drug price (eighth column) spends the revenue the screen frees on vouchers for households that do not use, or use but are not caught: π_V rises to 9.24 percent, drug use

falls by 42 percent, homelessness falls by 20 percent, and the share of children in a shelter falls by 19 percent. Now the higher π_V makes the parents gain as well, by 2.42 percent of their own lifetime consumption, and a newborn gains 6.45 percent, because the higher π_V houses more children. Drug use falls by about as much as with both held. Childhood homelessness falls because the additional spending on vouchers lifts other low-income households of child-rearing age that do not use drugs out of homelessness.

Letting the drug price clear instead, with π_V held at its Housing First level (ninth column), lowers the drug price by 6 percent. The revenue the screen frees then goes unspent: drug use falls by 20 percent, homelessness falls by 4 percent, and a newborn gains 0.98 percent.

Finally, letting both the drug price clear the drug market and π_V clear the budget gives the main experiment (last column). Under this configuration, Treatment First cuts drug use by 21 percent, from 8.92 to 7.07 percent of households, and the share of households with a SUD by 19 percent, from 3.83 to 3.08 percent of households. It also raises the share of households with a SUD who are in treatment, from 24.6 to 29.0 percent, because a household with a SUD that is in treatment and does not use passes the screen.[39] As users who lose their vouchers leave the programme, it costs less at a given π_V. Tax revenue also rises, mainly because more children start adult life with higher productivity, and to a lesser extent because fewer adults are unemployed owing to their SUD. Thus, π_V rises from 6.75 to 7.80 percent, by 16 percent, making staying clean of drugs even more desirable. At the same time, taking users out of the drug market lowers the drug price by 5 percent, which draws some households back.

In full general equilibrium, Treatment First also lowers homelessness by 11 percent, from 0.62 to 0.55 percent of households, for three reasons. First, households that stop using spend less on drugs, and thus more of them can house themselves. Second, less SUD means less unemployment and so less homelessness. Third, the vouchers Treatment First revokes from households with a SUD go, through a higher π_V, to other low-income households. For households aged 26 to 50, the years a child lives with them, homelessness also falls by 11 percent, with the share of children in a shelter falling from 1.03 to 0.92 percent.

These are long-run outcomes, but the transition does not qualitatively reverse them. One concern is that homelessness and childhood homelessness could rise in the first years after the reform, because the households that already have a SUD face losing their vouchers unless they enter treatment and stay sober, while the number with a SUD falls only as fast as recovery allows. As I show, this concern does not materialise: few households lose their vouchers, and those that stop using spend less on drugs and can afford to house themselves, so neither rises even in the first year (Section 6.4).

A newborn is better off under Treatment First by 2.57 percent of lifetime consumption, and its parent by 0.69 percent of its own. The gain of 2.57 percent is below the 6.45 percent of the second step, where the drug price is held, because the cheaper drug draws users back, which lowers π_V, and their use harms their children. The share of children living with a parent who uses drugs falls from 16.35 to 13.24 percent, and the share living with one who has a SUD falls from 5.82 to 4.75 percent.

Of the households that enter adult life at 26, 99.9 percent are better off under Treatment First than they would be in the same state under Housing First (Table 5). This is because an entrant has never had the disorder and holds no voucher, so the screen costs it nothing unless it chooses to use, while a voucher is easier to draw and the drug is cheaper. Across all households, 74 percent are better off and 3 percent worse off, and the rest are essentially unaffected. Finally, even 24 percent of those that have a SUD are better off.

6.3 Where the gain comes from

A newborn's gain under Treatment First is the change in (31), and it has four parts, two of which are externalities. Write ΔC for the change in the child's welfare in childhood, the first term of (31), and ΔA for the change in its welfare in adult life, the second.

Childhood its parent does not count. The parent values the child's childhood at the share ω_c; the share

[39] Under Treatment First a household with a SUD keeps its voucher by entering treatment and stopping. I also ran the experiment in which households with a SUD cannot respond at all: any use and the disorder itself fail the screen, in treatment or not, so treatment cannot help a household keep its voucher, although the government still pays for it. The results continue to hold: Treatment First then cuts drug use by 29 percent and the share with a SUD by 29 percent, homelessness falls by about as much as in the main experiment, by 11 percent, and a newborn gains at least as much. The results therefore do not depend on households with a SUD entering treatment and stopping.

Table 5: The long run under each policy

	No externalities					With externalities				
		Treatment First					Treatment First			
	Housing First	Both held	π_V clears	Price clears	Both clear	Housing First	Both held	π_V clears	Price clears	Both clear
Adults										
Drug price, benchmark = 1	1.03	1.03	1.03	0.99	0.99	1.00	1.00	1.00	0.94	0.95

In a shelter	1.01	0.96	0.95	0.98	0.98	1.03	0.95	0.83	0.98	0.92
Welfare										
CEV of a newborn, percent of lifetime consumption	–	−1.17	−1.09	−0.89	−0.74	–	2.82	6.45	0.98	2.57
Share of the newborn's gain that comes in childhood	–	–	–	–	–	–	86	59	102	64
Households entering adult life at 26 better off	–	0	1	0	18	–	0	100	5	100
All households better off	–	0	58	1	63	–	0	74	1	74
Households with a SUD better off	–	0	0	13	13	–	0	17	14	24

Notes: percent unless the row says otherwise; each column is a steady state. The first five columns are Housing First and Treatment First without the externalities, with the child appearing only as an adult. Under Housing First the drug price clears and π_V is the benchmark's. Under Treatment First, the drug price and π_V are both held at the first column's levels in the second column; the drug price is held and π_V clears the budget against the first column's net revenue in the third; the drug price clears with π_V held in the fourth; and both clear in the fifth. The CEV in the second to fifth columns is the newborn's value at 26, against the first column. Housing First, the sixth column, is the benchmark with the externalities. Treatment First screens with a detection rate of 20 percent. In the seventh column the drug price and π_V are both held at their Housing First levels, in the eighth the drug price is held and π_V clears, in the ninth π_V is held and the drug price clears, and in the last both clear; when π_V is held, the revenue the screen frees goes unspent, and when it clears, π_V holds net government revenue at its benchmark level. Children are those living with households aged 26 to 50, the years a child lives at home. The CEV is against the benchmark. A household is better off when its value under Treatment First exceeds its value in the same state under Housing First, with households weighted by the Housing First distribution.

$1-\omega_c$ of ΔC is the childhood externality, the budget and childhood homelessness externalities together: the consumption and housing a child gets when its parent spends less on the drug and is less often unemployed.

I split the change in adult life, ΔA, into two parts that add up to it exactly.

Better productivity at entry. The first part comes from how Treatment First affects the adult productivity distribution. To measure it, I take the distribution of adults at age $j = 1$ under Treatment First and compare it to the distribution of adults of the same age under Housing First. I value both distributions under Treatment First's policy, drug price and probability of drawing a voucher, so that the second part below equals the parent's own gain exactly. Under Treatment First, fewer households had a SUD, and thus fewer adults at age $j = 1$ carry the earnings penalty. I call this part ΔE, the improvement in welfare due to the gains in adult productivity. As in the case of childhood, it has two shares. The parent counts the share ω_c of it through the charge $D(y, d)$ in (24), and the rest, $1 - \omega_c$, is the earnings externality.

The newborn's own adult life under the policy. Here, I keep the Housing First distribution, with its distribution of entrants into adulthood and the earnings penalties they carry with them, and only change the policy. The same child, with the same starting productivity drawn under Housing First, then lives its adult life under Treatment First, where the drug is cheaper and it is easier to draw a voucher when sober, but with the screen in place. This is the policy's effect on every adult, because it includes the general-equilibrium effects when π_V or the drug price can adjust. This captures the gain ΔP, which is the change in the parent's own lifetime value under the different policy, with the distribution of entrants held at Housing First's. The child receives it J_K years into its life, so it enters the newborn's gain as $\beta^{J_K}\Delta P$.

What its parent does count. This is the part of the child's gain that the parent weighs in its own choices, and therefore, this part is not an externality.

ΔP is the change in the parent's value at $j = 1$ of (24) when the policy switches from Housing First to Treatment First, averaged over the households that Housing First's newborns are born into, so that the

same households are valued under both policies. ΔA is built from the same value at $j = 1$, the entrant's, discounted by β^{J_K} for a newborn, so the split of adult life is exact. For a newborn, $\beta^{J_K}\Delta P$ is the change in that value at a given starting productivity drawn under Housing First, so $\Delta E = \Delta A - \beta^{J_K}\Delta P$ is what the newborns' better starting productivity under Treatment First adds. In symbols,

$$\Delta W = \underbrace{(1-\omega_c)\,\Delta C}_{\text{childhood externality}} + \underbrace{(1-\omega_c)\,\Delta E}_{\text{earnings externality}} + \underbrace{\beta^{J_K}\Delta P}_{\text{own adult life}} + \underbrace{\omega_c\,(\Delta C + \Delta E)}_{\text{counted by the parent}} . \tag{32}$$

Table 6 reads each part off the benchmark's welfare curve, one after the other, so that the four sum to the newborn's CEV. Its last row adds the parent's own gain ΔP as a percent of the parent's own lifetime consumption, read off the curve for adult life, undiscounted, since the parent is at $j = 1$ when its child is born. The gain from the newborn's own adult life is smaller in absolute value than its parent's gain, for two reasons: the newborn receives it J_K years after birth, discounted, and its lifetime consumption, the base of the percent, includes its childhood as well as its adult life.

Table 6: Where the newborn's gain comes from

	Both held	π_V clears	Both clear
The newborn's gain ΔW, percent of lifetime consumption	2.82	6.45	2.57
Childhood its parent does not count, $(1-\omega_c)\Delta C$	2.20	3.47	1.50
Better productivity at entry its parent does not count, $(1-\omega_c)\Delta E$	1.06	1.00	0.46
The newborn's own adult life under the policy, $\beta^{J_K}\Delta P$	−0.75	1.54	0.43
What its parent does count, $\omega_c(\Delta C + \Delta E)$	0.31	0.44	0.19
The externality, the first two parts, percent of the gain	116	69	76
The parent's own gain ΔP, percent of the parent's lifetime consumption	−1.19	2.42	0.69

Notes: Treatment First against Housing First in the long run; the columns are the seventh, eighth and last of Table 5. The first row is the CEV of (30). The four rows under it sum to it: each is read off the benchmark's welfare curve after the ones above it. Childhood is the change in the child's flow at its weight $\xi - 1$, and better productivity at entry the change in its adult value from who enters; each is split into the share ω_c its parent counts and the share $1-\omega_c$ it does not. Better productivity at entry holds the policy and changes only who enters adult life; the newborn's own adult life holds who enters and changes only the policy, and equals the parent's own gain discounted to the child's birth. The parent's own gain is the change in its value at $j = 1$ when the policy switches from Housing First to Treatment First, with the distribution of entrants held at Housing First's, for the households Housing First's newborns are born into, as a percent of the parent's own lifetime consumption, undiscounted. It is larger in absolute value than the newborn's own adult life because the newborn receives the same gain J_K years later, discounted, and because the newborn's lifetime consumption, the base of its percent, includes its childhood as well as its adult life.

In the main experiment, the last column of Tables 5 and 6, the newborn gains 2.57 percent of lifetime consumption. Of that, 1.50 percent is childhood and 0.46 percent better productivity at entry, both of which its parent does not count. In all, three quarters of it is an externality. The rest is the newborn's own adult life under the policy, 0.43 percent, and the 0.19 percent that its parent does count, of childhood and of productivity at entry. Of the externality, the childhood part is the larger in every column: what the child gains at home accrues year by year for J_K years, while the earnings penalty reaches it once, at entry. The parents gain as well (the bottom row of the last column), by 0.69 percent of their own lifetime consumption, because the higher π_V and the cheaper drug outweigh the option the screen removes: in general equilibrium both the child *and* the parent gain.

With the drug price and π_V held, the first column, the externality is more than all of it, because the newborn's own adult life is a loss there, of 0.75 percent of lifetime consumption: the screen takes an option from every adult and gives nothing back, and the parents' own lifetime consumption falls by 1.19 percent. Recycling the savings, the second column, turns the newborn's own adult life into a gain of 1.54 percent and the parents' loss into a gain of 2.42 percent, since the vouchers go to households that do not use or are not caught; the cheaper drug then takes part of it back, in the last column.

6.4 The transition

To see what the reform does on the way to the long run, I compute the transition from Housing First to Treatment First. The transition starts from the benchmark, with the reform landing as an unexpected permanent shock at the start of the first year, and I simulate it for sixty years, all the way to the Treatment First steady state. Figure 3 shows what the transition looks like along eight key dimensions.

Panels (a) and (d) show drug use and the share of parents who use, respectively. Drug use falls on impact: 81 percent of its long-run fall happens in the first year. In the first year, the share of parents using drugs falls from 16.35 to 13.57 percent, above its long-run level of 13.24 percent. It stays above its long-run level until year 12, because it counts the parents who have a SUD when the reform lands, whose number falls only slowly (panel (b)). From then on it moves around its long-run level. The screen affects the decisions to go to treatment and to use drugs, both directly and through expectations. A voucher holder that uses risks losing its voucher within a year, and a household that uses risks having a voucher offer revoked later, when it may need one but have a SUD, since a disorder takes years to clear.

Panel (b) shows the share with a SUD. This share falls gradually, because recovery is slow: half of its long-run fall is done by year 11, and nine tenths by year 27. The households that still have a SUD keep demand for the drug up, and the drug price stays above its long-run level for 33 years (panel (c)). The elevated price deters households without a SUD, at every age: in the first decade the number of drug users without a SUD falls by up to 23 percent, against 18 percent in the long run.

Panels (e) and (f) show homelessness and the share of children in a shelter, respectively. Neither rises at any point. Homelessness falls from 0.62 percent of households to 0.60 percent by year 10 and 0.55 percent by year 60, against 0.55 percent in the long run, and the share of children in a shelter falls from 1.03 to 1.00 percent by year 10 and 0.92 percent by year 60, against 0.92 percent in the long run. Both could have risen, since the households that have a SUD when the reform lands face losing their vouchers unless they enter treatment and stay sober. They do not, for three reasons. First, few households lose their vouchers: one with a SUD keeps its voucher by entering treatment and not using, and the screen catches a user with a probability of only 20 percent a year, so at most 0.13 percent of households are excluded from the programme in any year. Second, drug use falls from the first year (panel (a)), so households spend less on drugs and have more left over to house themselves, and fewer acquire a SUD and experience longer unemployment. Third, after the first three years, when it is as low as 6.55 percent, π_V stays above its Housing First level of 6.75 percent, so the vouchers the screen frees go to other low-income households.

Panel (g) shows the CEV of each cohort by its year of birth. Children born at the reform gain 1.45 percent of lifetime consumption, less than the 2.57 percent of those born in the long run, for two reasons. First, they grow up while the share of households with a SUD is still close to its Housing First level, since it falls only as fast as recovery allows: from 3.83 to 3.47 percent in the first ten years, against 3.08 percent in the long run. This means that more children grow up with a parent who has the disorder, and more children enter their adult life with a lower productivity due to the earnings penalty. Second, π_V is lower in the first years than in the long run: between 6.55 and 6.90 percent in the first decade, against 7.80 percent. Part of what Treatment First adds to the budget is the taxes paid by adults who grew up without the earnings penalty, while those adults start working only J_K years after the reform. Until then, their parents are less likely to draw a voucher. The gain rises towards its long-run level for children born later, whose parents were themselves born after the reform.

Of the adults alive at the reform, only 11 percent are worse off under it, and even of those who have a SUD when it lands, 33 percent benefit, because the lower drug price more than offsets the loss from the sobriety requirement for some of them. Panel (h) repeats the comparison in every period of the path, with households in each state weighted as under Housing First. The share worse off stays between 2 and 11 percent, and the share of those with a SUD who are worse off falls from 67 to 50 percent as the price comes down further. Of the households entering adult life at 26, 33 percent are better off in the first year, when π_V is still close to its Housing First level, and 99.9 percent by year 59.

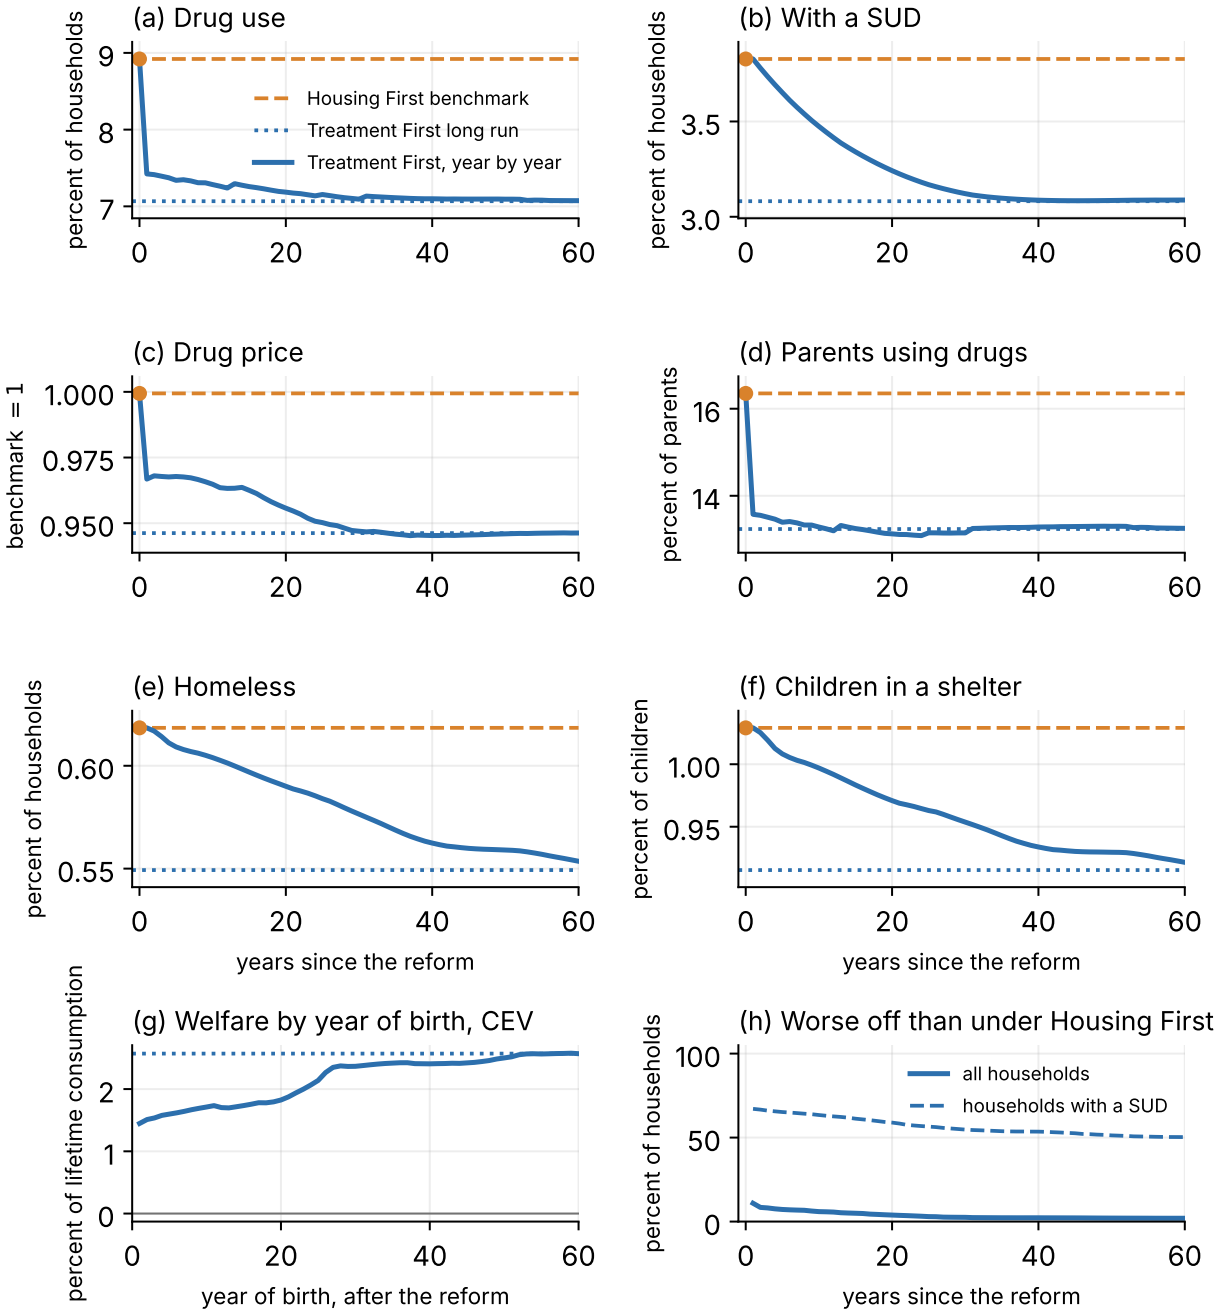

Figure 3: The transition from Housing First to Treatment First, quantitative model

Notes: panels (a) to (f) and (h) are by year since the reform, which lands at the start of year 1, with the benchmark as year 0; the dashed orange line is the Housing First benchmark, the dotted blue line the Treatment First long run and the solid blue line the path. In panel (h) the dashed line is the share of households with a SUD who are worse off. Children are those of households aged 26 to 50. Panel (g) is the CEV of each cohort born on the path, against the benchmark, by its year of birth. Panel (h) is the share of households worse off in each year of the path than in the same state under Housing First, weighted by the benchmark's distribution.

6.5 Alternative transitions

The main transition lets a household with a SUD keep its voucher by entering treatment and not using. This section asks what the first periods of the reform look like when households with a SUD cannot stop using, so that only after recovery can they stay sober and pass the screen. I consider three alternatives, each with the screen catching every user or catching 20 percent of users, and with the drug price and π_V clearing every period. In the first, the screen applies from day one of the reform, and the disorder fails it whether or not the household is in treatment. In the second, the reform is announced, but Housing First continues for five periods and the same screen starts in period six. In the third, the same screen applies from the reform, but for its first five periods a household in treatment keeps its voucher even if it uses drugs. Table 7 shows how homelessness, the share of children in a shelter and the welfare of children born at the reform compare with the Housing First benchmark in each, beside the main transition (first row).

Table 7: The first years of the alternative transitions

		Homelessness		Children in a shelter		Newborn's
	p_{det}	Largest rise	Periods above	Largest rise	Periods above	gain
Main transition	20	none	none	none	none	1.45
No exemption						
	100	13.6 (2)	1–15	10.8 (2)	2–11	6.57
	20	5.3 (6)	2–17	3.1 (5)	2–11	3.02
Announced five periods ahead						
	100	7.9 (10)	7–17	4.4 (9)	7–13	3.46
	20	3.3 (12)	7–19	0.9 (10)	8–13	1.91
Sobriety while in treatment exempt for the first five periods						
	100	5.5 (7)	7–14	2.0 (7)	7–10	6.20
	20	1.6 (11)	8–16	none	none	2.72

Notes: Each row is a transition from the Housing First benchmark to Treatment First with the drug price and π_V clearing every period, against Housing First's steady state. Main transition: Section 6.4, where a household with a SUD keeps its voucher by entering treatment and not using. In the other rows it cannot stop using, and the disorder fails the screen even in treatment: from the reform (no exemption), from period six with Housing First until then (announced five periods ahead), or from period six with treatment alone passing it until then (sobriety while in treatment exempt for the first five periods). p_{det} is the detection rate, in percent. Largest rise: the largest percent increase over the first fifteen periods, with its period in brackets. Periods above: the periods in which it is above Housing First. Children in a shelter is the homelessness of households aged 26 to 50. Newborn's gain: the CEV of children born at the reform, percent of lifetime consumption. When every user is caught, no drug price clears the long-run drug market, because drug use jumps as the price moves through the level that would clear it; those transitions end at the long-run solution that comes closest.

In the first alternative, how much the screen catches decides what happens along the way. Catching every user lowers homelessness by 30 percent and the share of children in a shelter by 31 percent in the long run, but it puts every voucher holder with a SUD out at once: homelessness rises by up to 14 percent and the share of children in a shelter by up to 11 percent, and they stay above their Housing First levels for 15 and 11 years, respectively, because π_V rises only as the savings accrue. Catching only one in five users lowers both in the long run too, homelessness by 11 percent and the share of children in a shelter by 11 percent, but it also raises them in the first years, though by less, because it puts fewer households out at once: homelessness rises by up to 5 percent and the share of children in a shelter by up to 3 percent. Even so, children born at the reform gain 6.57 percent of lifetime consumption when every user is caught and 3.02 percent when 20 percent are, against 1.45 percent in the main transition. They gain more because the screen deters more: a household with a SUD cannot stop using, so the disorder costs it its voucher until it recovers, while in the main transition the household keeps the voucher by entering treatment and not using. By period ten, 2.80 percent of households have a SUD when every user is caught and 3.24 percent when 20 percent are, against 3.47 percent, so fewer of these children grow up with a parent who has the disorder, and π_V is higher throughout their childhood.

Announcing the screen five periods before it starts lowers the rise but does not eliminate it. While

Housing First continues, households cut their drug use at once in anticipation of a screen that will catch every user, by 15 percent in the first period, and homelessness and the share of children in a shelter fall below their Housing First levels. Once it starts revoking vouchers, they rise by up to 8 and 4 percent, against 14 and 11 percent without the announcement. When it catches one in five users, they rise by up to 3 and 0.9 percent. Children born at the reform gain 3.46 percent of lifetime consumption when every user is caught and 1.91 percent when one in five users are. The first is less than the 6.57 percent without the announcement, because π_V does not rise until the screen starts and drug use falls by less in the first period than the 40 percent when the screen starts at once.

Exempting sobriety while in treatment for the first five periods lets a household with a SUD keep its voucher in those periods by entering treatment, even if it uses drugs, and more households do: 36 percent of those with a SUD are in treatment, against 25 percent under Housing First. When the screen catches one in five users, homelessness stays below its Housing First level for the first seven periods but rises above it by at most 1.6 percent after the exemption ends, and the share of children in a shelter never rises above its Housing First level. When every user is caught, homelessness stays below its Housing First level for the first six periods but rises above it by at most 5.5 percent after the exemption ends, and the share of children in a shelter by at most 2.0 percent. Children born at the reform gain 2.72 percent of lifetime consumption when one in five users are caught, more than the 1.45 percent in the main transition, although the screen catches one in five users in both. Here a household with a SUD cannot stop using, so once the exemption ends the disorder puts its voucher at risk until it recovers, while in the main transition the household keeps the voucher by entering treatment and not using. Starting to use therefore risks more, and fewer households use drugs: by period ten, 3.27 percent of households have a SUD, against 3.47 percent, so fewer of these children grow up with a parent who has the disorder. When every user is caught, they gain 6.20 percent.

7 Discussion and implications

To close, I return to the question I started with: should housing assistance require sobriety? I argue that the answer is "Yes" if the externalities on children are counted but "No" if the moral hazard argument is invoked, which is the argument that dominates the policy debate. Specifically, I show that although, in an economy without the externalities on children, Treatment First cuts drug use by 28 percent, a newborn is still worse off, because the screen takes away an option from households that weigh the risks correctly, while the budget gives back less than the screen takes.

I then demonstrate that drug use takes away consumption and housing from children and reduces their productivity as adults. But because a parent counts only the share ω_c of these costs, the deterrence the screen creates generates more gain to the child than cost to the parent, and welfare rises. With the drug price and π_V held, the parents lose 1.19 percent of their own lifetime consumption, about what they lose without the externalities, while a newborn gains 2.82 percent, so the reform raises welfare on net once the children are counted. With the budget rebalanced and the drug price clearing, as they would be after a real reform, Treatment First cuts drug use by 21 percent, lowers homelessness by 11 percent, and raises a newborn's welfare by 2.57 percent of lifetime consumption, three quarters of it an externality its parent does not count. Once general-equilibrium effects are accounted for, the parents gain too, because the higher π_V and the cheaper drug outweigh the option the screen removes. Along the transition, neither homelessness nor the share of children in a shelter rises, and children born at the reform gain 1.45 percent.

Three lessons follow. First, the arguments for Housing First and Treatment First made by different advocacy groups leave out the outcome that matters most: what happens to the children of the households a sobriety requirement deters from using, in what they consume while living with their parents, in whether they become homeless and in what they earn as adults.

Second, the model agrees with the micro evidence behind Housing First on the households it follows: housing, and a sobriety condition on it, raise the recovery of households with a SUD by about as much as in the trial that measures both, and losing a voucher raises the mortality of households with SMI by about as much as Housing First lowers it among homeless veterans with mental illness. As that evidence implies, those with a SUD lose from Treatment First: with the drug price and π_V held, as in a trial, which is too small to move either, 74 percent of those who have one when the reform lands are worse off, and even once

both clear, 67 percent are. The macro effects the trials do not capture, however, overturn the conclusions. The trials follow only households already in a bind: adults who are homeless, most with SMI and many with a SUD. They do not follow the households that could get into a bind but that the condition deters from starting to use drugs. Nor do they observe the vouchers the condition's savings buy for others, or the children's adult lives. Once those are counted, aggregate homelessness and childhood homelessness drop and welfare increases.

Third, homelessness and childhood homelessness do not fall along the transition if treatment and sobriety are not a real option for the households that already have a SUD. A temporary exemption for those with a SUD keeps the latter from ever rising and the former's rise small: if a household in treatment keeps its voucher, sober or not, for the first five periods, and the screen catches one in five users, the share of children in a shelter never rises above its Housing First level and homelessness rises by at most 1.6 percent, with newborns gaining even more than in the main transition.

A Calibration of the standard parameters

My full calibration contains many parameters, many of which are more conventional and used in many papers. Here, I show how I set those thirty-three parameters. I calibrate six of them internally and set the other twenty-seven externally from estimates in the literature or from statute. Table A1 and the entries below proceed in the same seven blocks. In each entry, I give the moment or source that pins down the parameter and the value of that moment in the data. For the internally calibrated parameters, the Model column also presents the model's performance.

None of these parameters are inert. They too matter for the experiments, but they are more standard and matter less for the results than the parameters that I covered in the main text. For instance, the discount factor affects how much weight households give to dying in a later period. The dispersion of productivity determines how many households are poor enough to be willing to risk having a disorder, and risk aversion determines how much households value the insurance of housing assistance.

Table A1: Standard parameters

Parameter	Description	Set	Moment and source	Data	Model	Value
Block 7: Preferences						
σ	Risk aversion	Ext.	Attanasio and Weber (2010)	2.00	n.a.	2.00
γ	Weight on housing services	Int.	Housing over expenditure net of drugs, CEX 2024	26.8%	26.2%	0.536
β	Discount factor	Int.	Wealth over output, BEA fixed assets	3.00	2.95	0.946
$\xi(j)$	Equivalence scale	Ext.	Square-root scale, OECD	1.41	n.a.	1.41
Block 8: Rental ladder						
h_2	Smallest rental size	Int.	Renters paying over half of income, SCF 2022	19.2%	25.8%	0.0407
h_3/h_2	Middle rung over the smallest	Ext.	Set	4.00	n.a.	4.00
h_4/h_2	Largest rung over the smallest	Ext.	Set	8.00	n.a.	8.00
Block 9: Earnings and employment						
J	Maximum age	Ext.	Age 85	60	n.a.	60
J_K	Years the child lives at home	Ext.	Parent aged 26 to 50	25	n.a.	25
J_R	Retirement age	Ext.	Age 66, SSA full retirement age	41	n.a.	41
$\varepsilon(j)$	Age profile of efficiency	Ext.	Hump peaking at age 56, Greenwood et al. (2025)	Profile	n.a.	Profile
ρ_y	Persistence of productivity	Ext.	Guvenen et al. (2023)	0.90	n.a.	0.90
σ_ζ	Standard deviation of its shocks	Int.	Bottom half's share of earnings, SCF 2022	17.2%	16.2%	0.413
ρ	Persistence of productivity across generations	Ext.	Solon (1992), Mazumder (2005)	0.50	n.a.	0.50
$\bar{\pi}^{eu}$	Job separation rate	Int.	Unemployment rate, BLS CPS 2014–24	4.9%	5.6%	0.0268
$\varpi(y)$	Separations by productivity	Ext.	Unemployment by education, BLS 2019	Profile	n.a.	Profile
$\bar{\pi}^{ue}$	Annual job-finding rate	Ext.	Krueger et al. (2014)	0.55	n.a.	0.55
p_{ui}	Share of separations that receive UI	Ext.	UI applicants among the unemployed, BLS 2022	0.30	n.a.	0.30
Block 10: Baseline survival and SMI onset						
$\bar{\phi}(j)$	Baseline survival by age	Ext.	US life table 2010, Arias (2014)	Profile	n.a.	Profile
$\varsigma_m(j)$	Age profile of SMI onset	Ext.	SMI prevalence by age, NSDUH 2024	Profile	n.a.	Profile
Block 11: Interest and taxes						
r	Risk-free rate	Ext.	Kaplan et al. (2020)	0.03	n.a.	0.03
φ	Tax progressivity	Ext.	Heathcote et al. (2017)	0.85	n.a.	0.85
τ_ℓ	Level of the labour income tax	Int.	Average labour income tax, McDaniel (2007)	22.4%	20.9%	0.894
τ_k	Capital income tax rate	Ext.	US long-term rate on gains and dividends	0.15	n.a.	0.15
Block 12: Social security benefits and programmes' rules						
$S(y)$	Social security	Ext.	SSA primary insurance amount	Statute	n.a.	0.90, 0.32, 0.15
$\underline{S}$	SSI floor over average labour income	Ext.	SSA federal benefit rate	0.177	n.a.	0.177
$\bar{\psi}_{ui}$	UI replacement rate	Ext.	Department of Labor, statutory rates	0.50	n.a.	0.50
$\bar{y}$	Cap on the UI earnings base	Ext.	Department of Labor, state benefit maxima	1.00	n.a.	1.00
κ_V	Voucher means test	Ext.	HUD rule	0.50	n.a.	0.50
κ_r	Tenant's rent, share of income	Ext.	HUD rule	0.30	n.a.	0.30
ϱ	Food stamp clawback rate	Ext.	SNAP statute, 7 CFR 273.10	0.30	n.a.	0.30
Block 13: Drug market						
J_E	Maximum age at which use can begin	Ext.	Model age 55, that is age 80	55	n.a.	55
ν_1	Supply shifter	Ext.	Normalisation, so $p_v = 1$	Norm.	n.a.	Norm.

Notes: the Model column is the Housing First benchmark. As in Table 3, I use n.a. whenever a parameter is set externally and thus has no moment to reproduce.

Block 7: Preferences. The four parameters in this block determine what households care about and what they are willing to give up in exchange.

σ, risk aversion. The risk-aversion parameter shapes the marginal utility of consumption, and through it, it affects the welfare comparisons in the experiments in this paper. When it is increased, households prefer smoother consumption, and therefore housing assistance as insurance is worth more to them. I set it to the standard value of two, following Attanasio and Weber (2010).

γ**, the weight on housing services.** It is the weight on housing in the bundle of consumption and housing, so it sets what a dwelling is worth against consumption, and that bundle is what the drug is weighed against. As γ rises housing is worth more relative to consumption, households buy more of it, and the share of spending that goes on housing rises with it. γ is chosen for the share it produces: shelter plus utilities take 26.8 percent of expenditure in the 2024 Consumer Expenditure Survey (CEX), which excludes illicit drug spending.

β**, the discount factor.** It sets how much households discount the future, and thus how much they save and how much the prospect of death deters them from using drugs. As it rises households save more, the wealth-to-output ratio rises and households are more deterred by death. It is chosen so that wealth over output matches the national accounts, a ratio of three, from the Bureau of Economic Analysis (BEA) fixed asset tables against National Income and Product Accounts (NIPA) output, both read at the 2023 vintage, the last year the fixed asset tables cover.

$\xi(j)$**, the equivalence scale.** The household's consumption and dwelling are shared with the child while it lives with its parent, and thus are divided by $\xi(j)$ to give what each member gets. Raise it and each member gets less of a given budget, and the child counts for more of the household, through the weight $\xi(j) - 1$ in (12). It is the square-root scale (OECD, 2013), $\sqrt{N(j)}$, where $N(j)$ in the model is set to two while the child lives with the parent ($j \leq J_K$), from the parent's age 26 to 50, and to one after the child has left ($j > J_K$).

Block 8: Rental ladder. These three parameters build the grid of dwelling sizes a household chooses from. Below the smallest rung is the shelter, h_1, which was calibrated in Block 2.

h_2**, the smallest rental size.** The size of the smallest dwelling is what determines how much of its income a poor household has to spend to avoid homelessness. When the smallest dwelling is larger, it is more expensive to rent, and thus more households are cost burdened and more likely to become homeless, and a voucher is worth more to them. It is chosen so that the fraction of renters paying more than half of their income for housing is similar to the data, 19.2 percent in the 2022 SCF; the model gives 25.8 percent.

h_3/h_2 **and** h_4/h_2**, the spacing of the ladder.** The two ratios here determine the amount of housing services obtained by renting the middle and largest dwelling options. Therefore, they affect what a household that can afford more than the smallest unit can rent. Larger ratios make each step up the ladder cost more to rent, and thus fewer households can afford the larger options. The two larger rungs are set at 4.00 and 8.00 times the smallest.

Block 9: Earnings and employment. This block has eleven parameters that govern the maximum periods of life a household can live, until what age it works, and what it can expect to earn while it is of working age. These parameters also set how persistent and frequent shocks to employment and productivity are.

J**,** J_K **and** J_R**, the length of life, of child rearing and of working life, respectively.** A household lives at most J periods, has its child at home for its first J_K of them and works until model age J_R, after which it retires on social security. J and J_R set the maximum number of years a household can live and work, respectively, and J_K sets how long a parent's drug use reaches its child, since the child lives with it during those J_K years. A higher J or J_R makes a disorder that shortens life or employment more costly, whereas a higher J_K makes the budget and childhood homelessness externalities last longer. I set $J = 60$, so that with $j = 1$ at age 26 the last age is 85, $J_K = 25$, so that the child lives at home while its parent is 26 to 50, and $J_R = 41$, so that retirement begins at age 66, the full retirement age under social security for those born between 1943 and 1954.

$\varepsilon(j)$**, the age profile of efficiency.** This is the deterministic hump in earnings over the life cycle. Without it every household with the same productivity would earn the same at every age, and the ages at which households are poor, and so at risk of homelessness and of using, would be wrong at both ends of working life. I take it as the exponential of a quadratic in age used by Greenwood et al. (2025), $\varepsilon(j) = \exp\{-(j-1)^2/1800 + (j-1)/30\}$ with $j = 1$ at age 26. It peaks at age 56, having risen 65 percent from age 26, and then falls 4 percent from the peak to age 65, the last working age.

ρ_y **and** σ_ζ**, the productivity process.** Log productivity is persistent but not permanent: it follows an autoregressive process with persistence ρ_y and shocks with standard deviation σ_ζ. σ_ζ is what decides how many households are poor enough to be at risk of homelessness, and the share of earnings that goes to the bottom half of working households falls as it rises. I set $\rho_y = 0.90$, the persistence of the income process in Guvenen et al. (2023). σ_ζ is calibrated to the bottom half's share of earnings among households aged 26 to 65 with positive wage income in the 2022 SCF, 17.2 percent.

ρ**, the persistence of productivity across generations.** The child's log productivity at entry into adulthood is drawn around its parent's with weight ρ and around the mean with weight $1 - \rho$, so ρ is how much of its parent's current productivity a child keeps. It is the channel through which anything that lowers a parent's productivity lowers its child's: a parent whose own productivity carries the penalty δ_d, because its own parent had a SUD, also passes a lower draw on to its child, so a parent's SUD lowers productivity beyond the next generation. Raise it and a child's prospects depend more on its parent's decisions, and the *earnings externality* grows. It is set externally at 0.50, between the intergenerational elasticities of earnings in Solon (1992) and Mazumder (2005).

$\bar{\pi}^{eu}$**, the job separation rate.** This parameter determines the chance that an employed household loses its job each year. It is scaled by $\varpi(y)$ in (21), so separations are likelier at low productivity. Raise it and more households lose work each year, so the unemployment rate rises with it. It is chosen to reproduce the aggregate unemployment rate in the Current Population Survey (CPS) of the Bureau of Labor Statistics (BLS) over 2014 to 2024, 4.9 percent, given the job-finding rate set externally below.

$\varpi(y)$**, separations by productivity.** This parameter tilts the separation rate across productivity, so that low-productivity households lose their jobs more often, which is what puts them at a higher risk of homelessness. A steeper gradient exposes low-productivity households to a higher chance of unemployment, and thus a higher risk of homelessness. It is normalised to average one across households, so that $\bar{\pi}^{eu}$ alone sets the aggregate unemployment rate. Each productivity node takes the unemployment odds of the education group it falls in, from the BLS 2019 annual averages of unemployment by educational attainment for ages 25 and over, with the education groups ordered along productivity by their median earnings.

$\bar{\pi}^{ue}$**, the annual job-finding rate.** This parameter is the probability that an unemployed household finds work each year it is unemployed. With the divisors κ_d^{ue} and κ_m^{ue} it sets how long an unemployed household with a SUD or SMI is expected to remain unemployed. When it is raised, unemployment spells are shorter on average, and thus fewer households are unable to pay rent and become homeless. I set it to 0.55 from the annual exit rate Krueger et al. (2014) estimate on matched CPS panels.

p_{ui}**, the share of separations that receive UI.** A household that loses its job draws UI for one year with probability p_{ui} and nothing otherwise. It sets how many of the newly unemployed fall straight to zero earnings, and how costly being unemployed is. I set it to 0.30, since in the BLS supplement to the CPS for 2022 about seven in ten unemployed people who worked in the past year did not apply for UI after losing their job.

Block 10: Baseline survival and SMI onset. These two parameters are the survival and the SMI-onset age profiles.

$\bar{\phi}(j)$**, baseline survival by age.** This is the baseline chance of surviving to the next age, before any multiplier. It is the base that every mortality multiplier in Section 5, for a SUD, homelessness and SMI, scales. Raise it and households expect to live longer, so the life a SUD puts at risk is worth more. I take the profile from the life table for the total population of the United States in 2010 (Arias, 2014), for ages 26 to 85.

$\varsigma_m(j)$**, the age profile of SMI onset.** This determines the shape of onset across ages, normalised to one at age 26, so that ω_m in Table 3 sets its level alone. It is here rather than in Table 3 because, like the age survival profile, it only sets the baseline. What actually affects the impact of Housing First versus Treatment First is ι, the multiplier a SUD puts on SMI onset, which is in Table 3. It is the onset that reproduces a log-linear fit to the share of adults carrying SMI at each age in NSDUH 2024.

Block 11: Interest and taxes.

r**, the risk-free rate.** This parameter sets the return on saving. A higher interest rate improves the return on savings, and thus households accumulate more assets, which help cushion them during spells of unemployment. I set it to three percent, from Kaplan et al. (2020).

φ**, tax progressivity.** This is the exponent on income in the tax schedule of Section 4.3, and it determines the progressivity of the labour income tax. When its value is lower, the tax system becomes more progressive. In that case, households with low incomes keep more of what they earn. It is set to 0.85, in line with Heathcote et al. (2017).

τ_ℓ**, the scale of after-tax labour income.** Given φ, this parameter sets how much of their labour income households keep after tax on average, so raising it lowers the tax liability. It does not move in the experiments: the budget is balanced by π_V instead. It is calibrated to an average labour income tax rate of 22.4 percent, which is what McDaniel (2007) measures for the United States and what Guvenen et al. (2023) use.

τ_k**, the capital income tax rate.** This parameter affects the after-tax return on savings. A higher capital income tax rate reduces the after-tax return to savings, and this discourages households from saving. I set it to fifteen percent, consistent with the statutory United States rate on long-term capital gains and qualified dividends for the middle of the income distribution, which the Internal Revenue Service (IRS) sets out in Topic 409 (`https://www.irs.gov/taxtopics/tc409`).

Block 12: Social security benefits and programmes' rules.

$S(y)$ **and** $\underline{S}$**, social security and its floor.** Retirement income follows the statutory primary insurance amount: it replaces a share of the household's income at its last working age, a share that falls at each of the two bend points of the Social Security Administration (SSA), up to the taxable maximum, with the SSI payment as a floor (the full function is detailed in footnote 16). As $S(y)$ rises the old are richer, so the value of a life still to be lived rises and with it the cost of a disorder that shortens it. The shares $\alpha_1, \alpha_2, \alpha_3$ are $0.90, 0.32, 0.15$ below the first bend point, between the two and above the second, respectively. The bend points k_1 and k_2 and the taxable maximum $y^{\max}$ are the SSA's 2024 dollar amounts divided by its average wage index, 0.22, 1.33 and 2.64, respectively. The floor, $\underline{S}$, is 0.18 of average labour income.

ψ_{ui} **and** $\bar{y}$**, UI.** The first parameter here sets the UI replacement rate, while the second parameter caps the earnings on which UI is paid. Raising either makes the first year out of work less costly for a household who lost their job, and thus makes it less likely that a household would end up in a shelter. I set them to fifty percent and one times average labour income, respectively, taking both from the statutory replacement rates and state benefit maxima that the Department of Labor compiles in its comparison of state UI laws (`https://oui.doleta.gov/unemploy/statelaws.asp`).

κ_V **and** κ_r**, the voucher rules.** These two set the income cutoff for eligibility and the tenant's rent contribution, respectively. Raise κ_V and more households are eligible, so more have a voucher to lose under Treatment First; raise κ_r and a voucher pays less, so losing one costs less. I take both from HUD's own rules: half of median income and thirty percent, respectively. The first is the very low-income limit HUD publishes annually with its income limits (`https://www.huduser.gov/portal/datasets/il.html`); the second is the share of its before-tax income a tenant pays towards the rent, the voucher paying the rest up to the payment standard, under the Housing Choice Voucher programme (`https://www.hud.gov/helping-americans/housing-choice-vouchers`).

ϱ**, the food stamp clawback rate.** This is the rate at which food assistance is withdrawn as income rises. Raise it and food assistance is clawed back faster, so it stops at a lower income and pays less to every household that still receives it. I set it to thirty percent, which is the statutory rule (7 CFR 273.10).

Block 13: Drug market. The two parameters in this block describe the rest of the drug market of Block 6. The first, J_E, fixes who can enter the market (footnote 21); the second is set so that supply equals demand in the benchmark, and is then held fixed.

J_E**, the last age at which use can begin.** This parameter is the last age at which a household without a SUD can start using; one that already has a SUD at that age can keep using. It decides who can

enter the drug market, and so how many households a policy that deters use can reach. As it rises, more old households can start using at little cost, since too little life remains for the disorder to damage (footnote 21), and the model produces too much old-age use. I set it to model age 55, the equivalent of age 80 when the model runs to age 85.

ν_1**, the supply shifter.** A pure normalisation, chosen so that supply equals demand at $p_v = 1$ in the benchmark, and kept fixed across experiments, in which the price is free to adjust. It normalises units, not behaviour.
