The stylized model

Demography and timing

Overlapping generations. A household lives two periods, young then old, and each cohort has unit mass. It has one child *while young*; the child leaves at the end of that period and enters the model as a young adult, so this period's children are next period's young and the cohort entering is unit mass forever. The equivalence scale is therefore ξ while young and 1 when old: the old carry no child, in the scale or in the objective.

The disorder is realised at the *transition* between the two periods, and survival over that transition depends on it. It cannot be realised inside the final period, where death costs nothing because nothing follows it.

Period 1

State. Permanent income y. An employment draw and, if income-eligible, a voucher draw give realised income and a rent multiplier (inc, r). Realised income is floored at $\underline{y}$. A voucher is means tested at y_V, arrives with probability π_V, and cuts the tenant's rent to κ_r of the market rent.

Choices. Drug purchase $v \geq 0$ at price p_v, housing $h \in \{h_{lg}, h_{sm}, h_{hl}\}$ — a large unit, a small unit, or the street, which is free and supplies h_{hl} — and saving $a' \geq 0$, subject to

$$c = \text{inc} - p_v v - \text{rent}(h, r) - a' > 0.$$

Flow utility. With $\varphi_h = \gamma(1-\theta)$, $\varphi_c = (1-\gamma)(1-\theta)$, $\varphi_q = \theta$ and $u(x) = x^{1-\sigma}/(1-\sigma)$,

$$X_P = \left(\tfrac{c}{\xi}\right)^{\varphi_c} \left(\tfrac{h}{\xi}\right)^{\varphi_h} (\bar{b} + v)^{\varphi_q}, \qquad X_K = \left(\tfrac{c}{\xi}\right)^{\varphi_c} \left(\tfrac{h}{\xi}\right)^{\varphi_h} \bar{b}^{\,\varphi_q},$$

$$\text{flow} = u(X_P) + \omega_c(\xi - 1)\, u(X_K) + \aleph.$$

c and h are divided by ξ and v is not, because the child consumes none of it: the child's bundle carries the Stone–Geary shifter $\bar{b}$ alone, so the drug reaches the child only by taking consumption out of the shared c. The child's weight is $\xi - 1$, so the household's weights sum to ξ — the same ξ that deflates its bundle. $\aleph$ is added once per household, not once per member.

Onset and mortality. The disorder arrives at the transition with probability $\pi(v)$, positive at any positive purchase and zero at $v = 0$. Survival is s_0 when clean and $s_1 < s_0$ with the disorder.

The problem. Choose (v, h, a') to maximise

$$\boxed{\mathcal{V} = u(X_P) + \omega_c(\xi - 1)u(X_K) + \aleph + \beta\Big[(1 - \pi(v))s_0 W_2(a', y, 0) + \pi(v)s_1 W_2(a', y, 1)\Big] - \beta\,\omega_c\,\Delta(y)\,\pi(v)}$$

Survival sits *inside* the expectation over the realised disorder, not outside it: written as $\phi\,\mathbb{E}W_2$, the disorder becomes something the household wants wherever $W_2 < 0$. The $v = 0$ branch is solved on its own, with the clean continuation and the voucher unrevoked, and the household uses if the best $v > 0$ beats it. The final term is the child's expected loss.

Period 2 — terminal

Employment is redrawn, at a worse rate with the disorder, and the voucher is redrawn subject to the policy rule. Assets are run down and nothing is bequeathed, so with $\text{cash} = Ra + \text{inc}$ and $\xi = 1$,

$$W_2(a, y, d) = \max_h \; u\big(c^{\varphi_c} h^{\varphi_h} \bar{b}^{\,\varphi_q}\big) + \aleph, \qquad c = \text{cash} - \text{rent}(h, r).$$

No drug choice, no child term, no recovery.

Policy. Housing First pays the voucher to every eligible household. Treatment First withdraws it from any household failing the sobriety condition *in the period the voucher is paid* — current use, or a current disorder. That single difference is the whole experiment.

The child

Income is inherited with persistence ρ, with the innovation that keeps the cross-section stationary:

$$\log y_c = \rho \log y + (1-\rho)\log \bar{y} - \delta_d \mathbf{1}\{d' = 1\} + \varepsilon, \qquad \varepsilon \sim N\big(0, (1-\rho^2)\sigma_y^2\big).$$

δ_d is the only inherited penalty: persistence alone delivers the homelessness odds ratio, so there is no separate homelessness penalty and the mixture has two types. The child is then run through the model as an adult at its own income, which is what gives it a disorder probability at all.

The parent internalises the *loss*, not the level:

$$\Delta(y) = \mathbb{E}\big[V_1(y_c) \,\big|\, \text{no penalty}\big] - \mathbb{E}\big[V_1(y_c) \,\big|\, \text{penalty}\big],$$

both expectations over the same kernel. V_1 appears on both sides, so this is a fixed point. It is a well behaved one: the $\aleph$ levels cancel in the difference, and what survives enters multiplied by $\beta\,\omega_c\,\pi(v)$. There is no survival factor on it — the child becomes an adult whether or not the parent lives, so s_d belongs on W_2 and on nothing else.

Lifetime utility

$V_1(y)$ is the household's *own* value: the maximised $\mathcal{V}$ with the internalised term $\beta\omega_c\Delta(y)\pi(v)$ added back, so that a planner counts the child once rather than once in full and again at ω_c. The childhood a cohort actually lives, at its parent's realised allocation, is

$$W_{\text{child}} = (\xi - 1)\big[u(X_K) + \aleph\big], \qquad \text{and} \qquad W = W_{\text{child}} + \beta V_1,$$

with childhood lived under the policy in force one period earlier and adulthood under the policy in force now. That asymmetry is what a static comparison sums away: the cohort the reform lands on has its childhood already behind it.

Consumption equivalents are CRRA, not log. Scaling c by $(1+\lambda)$ in every state scales both bundles by $(1+\lambda)^{\varphi_c}$, so every u term scales by $(1+\lambda)^{\varphi_c(1-\sigma)}$ while the $\aleph$ terms do not move:

$$\lambda = \Big(1 + \tfrac{dV}{U}\Big)^{\frac{1}{\varphi_c(1-\sigma)}} - 1, \qquad U = V - A, \qquad A = \aleph\Big(1 + \beta\big[(1-\pi)s_0 + \pi s_1\big]\Big),$$

which depends on the *level* through U, as the log formula never did.

What identifies what

γ	housing share of non-drug spending	θ	drug spending share among users
$\aleph$	value of a statistical life	π_{base}	disorder rate
h_{hl}	homelessness rate	ω_c	the child use gap
$\bar{b}$	drug participation	δ_d	the child's SUD odds ratio

σ, β, ρ, s_0, the unemployment rates, the unit sizes and the voucher rule are set rather than calibrated. Participation and the disorder rate are tied by sud = participation $\times\ \pi_{\text{base}}$, so they cannot be hit independently. ω_c acts in two places, the flow and the continuation, and the continuation half is $\Delta(y)$.
