Housing First or Treatment First? Ask the Kids, Not the Parents

Manuscript RED-D-26-00078

Response to the Associate Editor

Comments A1 to A20, responses in red

Thank you for a letter that was unusually specific about what a successful revision would have to contain. The three headings you set out, careful modelling of the mechanisms, careful modelling of the policies, and careful quantification, are how I organised the revision.

One note before the comments. The paper has a new title: it was submitted as *Housing First or Treatment First?* and is now *Housing First or Treatment First? Ask the Kids, Not the Parents*. The reason is the substance of the revision. The answer now turns on the children, through the intergenerational linkage that your A6 and Referee 2's comment C3 point to, and no longer on a loss of consortium added to welfare after the model is solved (A9).

What changed, under your three headings. On the mechanisms, Section 3 is a new two period model, calibrated, that isolates one mechanism: drug use concentrates at the bottom of the income distribution because the mortality risk of a substance use disorder (SUD) cannot be insured, while its unemployment risk can. The quantitative model drops most of the ingredients you questioned in A2 to A7: labour supply, homeownership, the clearing of house prices and rents, the separate unemployment insurance (UI) state and the type dependent transfers. It keeps general equilibrium, now in the drug price and the government budget (A5), and builds the link between generations that the previous draft only described (A6). It also drops the loss of consortium, and the fiscal cost the previous draft charged for each homeless household and each household with a SUD (A15). It adds serious mental illness (SMI), treatment as a choice, and children who share their parent's consumption and dwelling and whose adult productivity depends on their parent's SUD. No preference parameter varies with the disorder, SMI, income or housing. On the policies, Treatment First now requires a household with a SUD to be in treatment, and its drug test catches only some users, costs the government money, and excludes those it catches for a time. On the quantification, every internally calibrated parameter is reported with its data and model moment, the 26 parameters that carry the story are separated from the 33 standard ones, and Section 5.2 validates the model on moments it was not fitted to, among them Costantini's (2025) Housing First estimate, which you pointed to, and the contrast between conditional and unconditional housing in Milby et al. (2005), the trial Referee 2 pointed to.

The answer has changed with the model. Moral hazard alone does not justify conditionality: with the externalities on children removed, a newborn is worse off under Treatment First, by 1.09 percent of lifetime consumption, even when the savings from the drug test buy vouchers for other households. With them, in the main experiment, where the drug price and the probability of drawing a voucher both clear, Treatment First cuts drug use by 21 percent and homelessness by 11 percent, and raises a newborn's welfare by 2.57 percent of lifetime consumption. Three quarters of that gain is an externality on the child that its parent does not count, and in general equilibrium the parents gain too, by 0.69 percent of their own. The paper now also solves the transition, starting from the benchmark distribution. In the main transition neither homelessness nor the share of children in a shelter rises in any year, and children born at the reform gain 1.45 percent. In the alternative transitions, where households with a SUD cannot stop using, homelessness does rise for a time (Section 6.5).

Careful modelling of the key mechanisms

A1 A stylized model to convey the mechanisms

> *"In order to convey the different mechanisms of the paper, it would be helpful to provide a section with a simplified version of the model as suggested by both R1 and R3. The sheer number of moving parts are currently obfuscating the economics of the paper. . . . Derive basic model predictions on the relationships between the key model outcomes (income, unemployment, housing, drug use) and show these align with a few stylized facts."*

Done. Section 3 is a stylized model with two periods of thirty years each, a continuum of households whose productivity is fixed over life and lognormal across them, one asset, and a choice of whether and how much to use. Using carries the risk of a SUD, and a SUD brings two risks: a lower chance of surviving into the second period and a higher chance of being out of work in it. The model is dynamic rather than static, which is the point of Referee 1's comment 1(e): the cost of a SUD arrives in the second period, so the decision to use is a decision about a continuation value. It is also calibrated, to the same United States data as the quantitative model (Tables 1 and 2), and its five internally calibrated parameters hit their targets exactly, so its results are numbers rather than signs.

It is built to show one thing: why drug use concentrates at the bottom of the income distribution. Fewer than one in ten adults have a drug use disorder, mild included, which is what the paper counts as use, and the average user's income is 0.74 of the population average in the 2024 National Survey on Drug Use and Health (NSDUH). In the model drugs are a luxury good, so without consequences use would concentrate at the top: the average user would earn 3.51 times the population average. Figure 1 then turns on each risk on its own. The risk of dying alone takes the average user to 0.64 times the average at its calibrated strength. The risk of unemployment alone leaves it at 3.51 even at twice its calibrated strength, because a household can save against it, so the loss is roughly proportional to its income. Death cannot be insured against, and what it destroys grows with income. With saving switched off, unemployment reverses the gradient as well, because the loss from losing a job then grows with income too. Footnote 10 reports the same result in a version with housing, a shelter, UI and vouchers.

This motivates two decisions in the quantitative model, which keeps the stylized model's preferences and its two risks. No preference parameter varies with income (A8): the income gradient comes from the mortality risk. And the mortality multiplier of a SUD is calibrated to the income of users relative to the average, because it is the parameter that decides how far down the income distribution use sits (Block 1 of Section 5.1). The quantitative model falls short of that target: users earn 62 percent of the average, against 74 percent in the data.

On the stylized facts: the two above open Section 3. Figure 2 in Section 5.2, which is not targeted, shows the share of households that use drugs at each level of income relative to the mean, in the quantitative model and in NSDUH 2024. Use is highest at the bottom and lowest at the top in both: 18.3 percent against 13.7 below 0.22 of the mean, and 4.2 against 4.8 above 1.62 times it. Between 0.43 and 1.62 times the mean, use in the model is flatter and lower than in the data, 5.9 to 6.3 percent against 7.2 to 10.2. Both differences, more use at the bottom and less in the middle, lower users' income in the model, which is why it falls short of its target. Unemployment among households with a SUD is 14.5 percent in the model against 16.2 in NSDUH 2024 (Table 4, Block 2), and the shares of the homeless with a SUD and with SMI are calibration targets (A13 and A16).

[Still open.] The stylized model derives one of the relationships you list, between income and drug use. It takes the unemployment risk of a SUD from the data and leaves housing out, since its sole purpose, as the introduction says, is to show why the income gradient reverses. The relationships with unemployment and housing are shown only in the quantitative model.

This is in Section 3 (Tables 1 and 2, Figure 1), with the facts in Section 5.2 (Figure 2 and Table 4).

A2 Is modelling unemployment insurance expiration important?

"Is it important to model the expiration of unemployment insurance?"

[Conceded.] Not as a state of its own, and it is no longer one. In the previous draft a household that drew UI kept it for its whole spell, which needed a separate state. UI now lasts one year: a share of those who lose their job receive it in their first year out of work, and after that no unemployed household receives UI. This is folded into employment status, which takes three values: employed, insured in the first year out of work, and uninsured (equation 13, Section 4.3). Nothing about it has to be identified from data on drug use: the replacement rate and the cap come from state law as the Department of Labor compiles it, and the share insured from the Bureau of Labor Statistics (Blocks 9 and 12 of Appendix A).

I keep UI in this simple form because the paper's mechanism contrasts the unemployment risk of a SUD, which households can insure, with its mortality risk, which they cannot, and UI is one of the ways the first is insured, together with saving and food assistance. Because it stops after a year, a household whose SUD keeps it out of work for longer spends the extra time without it, and a household out of work longer is likelier to lose its housing (Block 2 of Section 5.1).

This is in Section 4.3 and Appendix A.

A3 The role of labour supply

"What is the role of labor supply in this framework?"

[Conceded.] None in the new paper, because it is no longer in the model. Earlier versions solved the model with endogenous labour supply, and with rents, homeownership and house prices. These margins had a negligible effect on the results, so I removed them (footnote 19, Section 4.4). An employed household now supplies its labour inelastically (Section 4.1).

What the model keeps is employment, which is not chosen: a household loses and finds jobs at rates that depend on its state. A SUD and SMI each make a job harder to find, and homelessness makes a job both easier to lose and harder to find (equation 21, Section 4.8). The SUD and SMI divisors are calibrated to the shares of the homeless with each condition (Blocks 2 and 3 of Section 5.1), the penalty of homelessness is set from Desmond and Gershenson (2016), and the unemployment rate of households with a SUD is a validation moment (A13).

This also bears on Referee 3's minor comment 1, which asked why the labour supply elasticity plays no clearer role when the budget is balanced with labour taxes. The budget is no longer balanced with taxes. The tax parameters are held at their benchmark values in every experiment, and the probability of drawing a voucher, π_V, adjusts so that net government revenue stays at its benchmark level (Section 4.11). No experiment raises a labour tax.

This is in Sections 4.1, 4.4 and 4.11.

A4 Why homeownership rather than homeless against housed?

"Why do we need the role of homeownership, and not simply the difference between homelessness and houses?"

[Conceded.] It is not needed, and it is gone, together with house prices (footnote 19). The housing choice is now close to what you suggest, a shelter against renting, and the rent per unit of housing is held at its benchmark value in every experiment (Sections 4.4 and 4.5). The shelter is literal homelessness, sleeping rough or in an emergency shelter, and its service flow is calibrated to the homelessness rate (Block 2 of Section 5.1).

Renting comes in three sizes rather than one, so that a household that can afford more than the smallest unit can rent more (Block 8 of Appendix A). The smallest size sets how much of its income a poor household must spend to stay housed, which is what Treatment First puts at stake when it conditions the voucher. It is calibrated to the share of renters paying more than half their income in rent, 19.2 percent in the 2022 Survey of Consumer Finances (SCF) against 25.8 in the model; the two larger sizes are set, not calibrated, at four and eight times the smallest. With these, 58.7 percent of housed households spend more than thirty percent of their income on rent, against 43.2 percent of renters in the SCF, and a voucher holder pays 39.0 percent of its income in rent, against 31.2 in the Picture of Subsidized Households of the Department of Housing and Urban Development (HUD), because a holder that rents above the fair market rent pays the difference itself (Table 4, Block 3). Referee 2's detail comment noted that the housing grid had seven points, of which three were calibrated; it now has four, of which two are calibrated.

This is in Sections 4.4 and 4.5, Block 2 of Section 5.1 and Block 8 of Appendix A.

A5 Why full general equilibrium?

"Why does the policy analysis require a full general equilibrium model? Many long-run partial equilibrium outcomes appear nearly identical to the general equilibrium ones. Do account for the changes in the government, and ideally for the adjustment in drug prices (See R1 Comment 1c) not necessarily in terms of housing prices and rents."

Done as you specify. House prices and rents no longer clear: there is no homeownership, and the rent is fixed (Section 4.4). Two objects clear instead. The government holds its net revenue at the benchmark level through the probability of drawing a voucher, π_V, with taxes unchanged (Section 4.11). And the drug price clears a supply curve whose price elasticity is 1.46, the estimate of Mace et al. (2020) for cannabis in Washington State (Section 4.12, Block 6 of Section 5.1). I know of no direct estimate for an illicit drug. Cannabis is the closest market I found, because it is still a Schedule I substance at the federal level, so its suppliers operate under federal prohibition. Their estimate is over a month, and the paper notes that the long run elasticity of an illicit supply is likely higher, in which case the drug price would fall less (footnote 31).

Both matter, which is why the policy analysis needs them, and Table 5 adds them one at a time so that the reader can see by how much. With the externalities on children and both held at their Housing First levels, Treatment First cuts drug use by 43 percent, a newborn gains 2.82 percent of lifetime consumption, and the parents lose 1.19 percent of theirs. Letting π_V clear spends the screen's savings on vouchers for other households: the newborn's gain rises to 6.45 percent, and the parents gain 2.42 percent. Letting the drug price clear as well brings the fall in drug use down to 21 percent, because the price falls by 5 percent and draws some households back into use. In the main experiment, with both clearing, a newborn gains 2.57 percent and the parents 0.69 percent. Holding both at their Housing First levels doubles the fall in drug use and gets the

sign of the parents' welfare wrong.

This is in Sections 4.11 and 4.12, with the results by step in Section 6.2 and Table 5.

A6 Intergenerational transmission discussed without intergenerational linkages

> *"Why is there a discussion on intergenerational transmission in Section 4.1.3, without intergenerational linkages?"*

[New result.] You were right that the previous draft discussed intergenerational transmission with nothing in the model behind it. Its Section 4.1.3 described permanent productivity as evolving across generations, but newborns drew it from an exogenous distribution, so nothing a parent did reached its child. Referee 2 (comment C3) pointed towards a real linkage, since parents care about their children. I built one, and it now decides the paper's answer, which is why the title changed.

There are three links. First, the child lives with its parent for its first 25 years and shares the parent's consumption and dwelling, but not the drug. Every unit a parent spends on drugs, and every unit of earnings it loses while a SUD keeps it unemployed, is consumption and housing the child goes without, and a homeless parent takes its child into the shelter (Section 4.2). Second, a child whose parent had a SUD at any point while it lived at home starts adult life with its productivity lowered by δ_d, for life, and since a child's productivity is drawn around its parent's, the penalty carries down the lineage (equation 22, Section 4.8). Third, the parent values its child, but imperfectly, with the weight ω_c, both in the flow of childhood and in what its disorder costs the child's adult life (Section 4.10). The share it leaves out, $1 - \omega_c$, is an externality. This gives three externalities on the child: the budget, earnings and childhood homelessness externalities.

The penalty and the weight are set from evidence. $\delta_d = 0.24$ is the earnings loss at age 32 that Nilsson (2017) measures for children of mothers under 21 exposed in the womb to a Swedish alcohol experiment. To my knowledge it is the only natural experiment estimate of how a parental substance shock reaches a child's adult earnings, although exposure in the womb does not map one to one into a parent's disorder after the child is born (Section 2). It is checked indirectly: in the model, a child of a parent with a SUD has 1.46 times the odds of acquiring one, at the low end of the 1.44 to 2.51 in Mellentin et al. (2016) and Yoon et al. (2013), and with the penalty switched off the odds ratio is 1.02 in the economy without the externalities, so the transmission runs through δ_d (Table 4, Block 6). The weight ω_c is calibrated, to 0.085, from behaviour. In NSDUH 2024, an unmarried adult living with one other adult and no child is 17.5 percent more likely to have used illicit drugs in the past year than a lone parent living with one child, reweighted to the same age, sex, marital status and family income. ω_c is set so that removing the parent's concern for its child raises drug use in the model by as much, 17.7 percent (Block 5 of Section 5.1). And 5.8 percent of children in the model live with a parent who has a SUD, against 4.6 percent in NSDUH 2024 (Table 4, Block 6).

How much rests on the linkage is shown directly. The first five columns of Table 5 remove the children: the parent gives them no weight, their productivity does not depend on the parent, and childhood is not counted. A newborn then loses under Treatment First in every configuration, by 1.17 percent of lifetime consumption with the drug price and π_V held and by 0.74 percent with both clearing. With the children, it gains 2.57 percent in the main experiment, and Table 6 shows that three quarters of that is the externality: 1.50 percent from childhood and 0.46 percent from better productivity at entry. With $\omega_c = 0.69$, the weight Nishiyama (2000) estimates and the upper end of the literature, a newborn still gains, by 3.18 percent, but only 23 percent of the gain

is then an externality (footnote 28). Referee 2 expected the channel to amplify the gains from reducing drug use. In this model it decides their sign.

This is in Sections 4.2, 4.8 and 4.10, Block 5 of Section 5.1, Block 6 of Section 5.2, and Sections 6.2 and 6.3 (Tables 5 and 6).

A7 Lump sum transfers and type dependent bequests

> *"Incidentally, how are the lump-sum transfers determined as a function of types? And why is it important that the bequests are type-dependent?"*

[Conceded.] It was not important, and both are gone. In the previous draft every living household received a transfer each period, financed by the estates of the dead, and the transfer rose with its productivity. Now only a household entering adult life receives anything from the estates: a one time endowment, T_0, the same for every entrant, and the government collects the rest (Section 4.3 and equation 26). T_0 has a job in the calibration: it sets how likely a young adult is to end up in a shelter in its first years, and it is calibrated to the share of the homeless aged 25 to 34, 26.0 percent in HUD's 2024 point in time (PiT) count against 26.4 in the model.

This is in Section 4.3 and Block 2 of Section 5.1.

A2 to A7 Simplify the secondary dimensions, and model the joint process in more detail

> *"Each of these model ingredients seem to be of lower importance relative to modeling of the joint process of homelessness, addiction, and income. I would prefer to see more detailed modeling of the key interactions of homelessness, addiction, and income, while simplifying the framework in secondary dimensions. While one can include additional features in a more detailed model in the appendix for sensitivity analysis, the paper would benefit from a more focused analysis in the body of the paper."*

Of the ingredients in A2 to A7, labour supply, homeownership, the clearing of house prices and rents, the separate UI state and the type dependent transfers are cut or reduced to their simplest form. So is one dimension of the drug choice: the chance that use leads to a SUD no longer rises with how much a household uses (footnote 20). Two are kept, for the reasons in A5 and A6: general equilibrium, now in the drug price and the budget rather than in housing, and the link between generations, which is now built into the model. The cut margins are not carried in an appendix: footnote 19 states that they had a negligible effect on the results in earlier versions, and the paper does not show those runs.

The joint process of homelessness, drug use and income is modelled in more detail, and its links run both ways. A SUD makes a job harder to find, and a household out of work is likelier to lose its housing. Homelessness in turn makes a job easier to lose and harder to find, raises mortality, and lowers the chance of recovering from a SUD (Sections 4.5, 4.6 and 4.8). SMI is a state of the model: a SUD makes it more likely to start, and it makes a job harder to find, raises mortality and makes recovery from a SUD less likely (Section 4.7). Treatment is a choice that raises recovery (Section 4.6). And a parent's drug use and SUD reach its child's consumption and housing, and its SUD the child's adult productivity (A6). Each hazard is anchored on, or checked against, a clinical or epidemiological estimate (Section 2 and Blocks 2 to 4 of Section 5.1).

This is in Section 4 and Section 5.1.

A8 Preferences: keep the weights invariant and vary b instead

> *"A parsimonious way that came to my mind is to keep the Cobb-Douglas weights invariant to addiction but let the marginal utility vary by addiction by changing the parameter b decrease by addiction status."*

The Cobb–Douglas weights are now invariant to the disorder, as you suggest, and so is b: no preference parameter varies with the disorder, SMI, income or housing (equations 11 and 12, Section 4.2). SMI does not enter the utility function at all (Section 4.7). The one term in flow utility beyond the parent's and the child's bundles and the value of being alive is the utility cost of a year in treatment, which a household pays only if it chooses treatment.

I did not let b fall with the disorder, because of the concern behind your comment and behind Referee 2's comment C5 and Referee 3's comment M2(a). Utility rises with b, so if b fell with the disorder, a household that acquired one would also have its utility from a given bundle lowered by assumption. A policy that prevented disorders would then raise welfare through that assumption as well as through behaviour. With preferences fixed, a SUD costs a household only through what it does to its budget and to the hazards it faces: a higher chance of dying, a job that is harder to find, a higher chance of SMI, and, for its child, a lower adult productivity. Each of these is set from, or calibrated to, data (Section 5.1).

Two consequences follow. First, the income gradient in drug use cannot come from preferences that differ across households, which is how the literature has produced it, with preferences that differ by education (Greenwood et al., 2025); it comes from the uninsurable mortality risk of a SUD, as the stylized model shows (A1). Second, the effect of housing on drug use cannot come from a preference either. It runs through the hazards a household faces, among them the chance of recovering, which is lower in a shelter (A13).

[Still open.] The paper does not solve the version you suggest, with b falling with the disorder, so it does not report how the results change under it. Its robustness to preferences is two checks: the qualitative results of the stylized model hold with log utility (footnote 8), and the parent's weight on its child, the preference parameter that decides how much of the gain is an externality, is raised to 0.69 in footnote 28 (A6).

This is in Sections 4.2 and 4.7.

A9 Loss of consortium is ad hoc; present welfare and mortality separately

> *"The consortium adjustment modeling also seems very ad-hoc while at the same time mattering a lot of the welfare ranking as noted also by the Referees. A possible way to address this would be to instead present the policy consequences along two different dimensions, the welfare consequences of equation (30) and the mortality consequences."*

[Conceded.] The loss of consortium is gone. Referee 1's version of the objection, that the truly conservative value for a parameter with no source is zero and that zero reversed the ranking, was right. Nothing is now added to welfare after the model is solved. Welfare is the newborn's expected lifetime value in the model, childhood included (equations 30 and 31, Section 6.1), and a death is valued only for what it costs within the model, chiefly the flow value of being alive, $\aleph$, which is calibrated to a value of a statistical life (VSL) of 80 times average labour income, 81 in the model (Block 1 of Section 5.1).

The case for Treatment First now rests on something the model contains. With the children removed, a newborn loses under Treatment First; with them, it gains, and Table 6 splits the

gain into the part its parent counts and the externality (A6). Referee 2's other suggestion, a disamenity that a large homeless population imposes on everyone else, is not in the benchmark. I solved the model with one, at the value in the contingent valuation of Loubière et al. (2020), about 0.2 percent of average earnings a year, and no long run gain in Table 5 moves by more than 0.14 percentage points (footnote 4).

[Still open.] The paper does not report the mortality consequences of the policies as a separate dimension. I did not add them because your suggestion was a way to keep an ad hoc valuation of deaths out of the welfare ranking, and with the adjustment gone the welfare numbers no longer contain one. The model's mortality is checked instead against the evidence on losing housing: with the drug price and π_V held, losing a voucher raises the three year mortality of households with SMI by about 3.6 percentage points, against the 4.6 by which Housing First lowers it among homeless veterans with mental illness in Costantini (2025) (Table 4, Block 7; see A14).

This is in Section 6.1 and Block 1 of Section 5.1, with the disamenity in footnote 4.

Modelling of the policies

A10 Treatment First actively treats; the model has no treatment

> *"Modeling 'Treatment First' as a voucher program that depends on sobriety seems to omit key characteristics. As R1 Comment 1 discusses, the program actively aims to cure substance use disorder before housing individuals. The policy itself has a direct role in impacting the transition out of addiction."*

[Conceded.] You and Referee 1 (comment 1(b)) were right: a policy named Treatment First contained no treatment, and recovery could not be chosen. It depended only on luck and on housing.

A household with a SUD now chooses each year whether to be in treatment (Section 4.6). Treatment doubles its chance of recovering, which is how much medication for opioid use disorder raises remission (Paul et al., 2024), and randomised trials of agonist medication against placebo find at least as large an effect on abstinence (Fudala et al., 2003). It costs the household utility, and that cost is calibrated to treatment take up: 24.5 percent of adults with a SUD received treatment in the past year in NSDUH 2024, against 24.9 in the model. The government pays for treatment under both policies, \$9,426 a year, 8.4 percent of average earnings, the cost of a residential treatment episode in Roebuck et al. (2003), so treatment competes with vouchers in the budget (Block 4 of Section 5.1). Recovery also depends on housing and on SMI: it is less likely in a shelter, by a multiplier calibrated to Milby et al. (2005), and less likely with SMI.

Treatment First now requires treatment: a household with a SUD fails the condition unless it is in treatment and does not use, as the July 2025 executive order directs and as the guidance implementing it requires of drug free housing (Section 4.9). In the main experiment, the share of households with a SUD who are in treatment rises from 24.6 to 29.0 percent (Table 5). The policy's effect on recovery is checked against Milby et al. (2005), the one trial that compares housing contingent on abstinence with housing without conditions: in the first year of Treatment First, voucher holders with a SUD recover 1.40 times as fast as housed households with a SUD and no voucher, against a ratio of 1.26 in the trial's weeks of abstinence (Table 4, Block 8). The results do not depend on households with a SUD entering treatment and stopping: when

treatment cannot help a household with a SUD keep its voucher, Treatment First cuts drug use by 29 percent and homelessness by 11 percent, and a newborn gains at least as much (footnote 38).

This is in Sections 4.6 and 4.9, Block 4 of Section 5.1 and Block 8 of Section 5.2.

A11 The policy is unlikely to be perfectly enforceable

> *"Moreover, the policy is unlikely perfectly enforceable. R1 Comment 4 suggests additional features of 'Treatment First' that are of first-order importance for the policy evaluation."*

Done. Under Treatment First, voucher holders and households that draw a voucher are tested, and one that fails the condition is caught only with some probability, so a user can keep its voucher (Section 4.9). The detection rate is 20 percent a year, set so that the screen deters use as much as the closest evidence on a drug test with a severe penalty, the US military's random testing. Mehay and Pacula (1999) find that it reduced past year marijuana use among the service members who stayed by 61 percent, and in the model 62 percent of the users who face the screen stop when it is introduced. Each test costs the government $35, 0.031 percent of average earnings, the upper end of the estimates (Legislative Budget Board, 2013), so testing competes with vouchers in the budget. A household that is caught loses its voucher and is excluded from the programme, returning to the lottery with probability one third a year. That is an expected exclusion of three years, the period for which the Housing Choice Voucher programme already bars a household evicted for drug related criminal activity.

The results hold at half the detection rate. At 10 percent, 41 percent of the users subject to the screen stop on impact, inside the 11 to 45 percent range that Mehay and Pacula find once those who left the military are counted. In the long run, Treatment First then cuts drug use by 14 percent and homelessness by 6 percent, and a newborn gains 1.65 percent, against 2.57 at the calibrated rate (footnotes 33 and 35). The previous draft's assumption, that every user is caught, appears in the alternative transitions, where households with a SUD also cannot stop using (Section 6.5, Table 7). There, with no exemption for treatment, catching every user raises homelessness by up to 14 percent in the first years, against up to 5 percent when one user in five is caught, so how much the screen catches decides what happens along the way.

[Still open.] Three of Referee 1's points in comment 4 are not in the paper. There are no false positives: a household that does not use, and is in treatment if it has a SUD, is never flagged, since, as Section 6 puts it, a positive screen is confirmed in a laboratory before it has consequences. There is no stigma or administrative burden beyond the cost of the test; for a household with a SUD, the cost of complying is entering treatment, whose utility cost is calibrated to take up (A10). And sensitivity to the parameters that are hard to identify, comment 4(d), is shown only through single robustness runs (A18), not a systematic exercise.

This is in Section 4.9, in the paragraph on the screen at the start of Section 6, and in Section 6.5.

Quantification

A12 Model fit never shown; untargeted moments missed

> *"Both the model quantification and model validation are well below the bar for publication. The paper never shows the model fit of the quantitative model and the model does not match up to non-targeted moments, casting doubt on any counterfactual policy experiments."*

[Conceded.] You were right on both counts. The fit is now shown in full. Table 3 reports, for each of the 26 parameters that carry the story, the moment, its source, its value in the data and in the model, and the parameter's value; Table A1 in Appendix A does the same for the 33 standard parameters. Of the 59 parameters, 21 are calibrated internally, and every one of them has its data and model moment side by side, so the reader can judge the fit. The two largest misses, in percentage points, are stated in the text: users earn 62 percent of the average in the model against 74 percent in the data (Block 1 of Section 5.1), and 25.8 percent of renters pay more than half their income in rent against 19.2 percent (Block 8 of Appendix A). The calibration targets only the average income of users; use by income in the model is highest at the bottom and lowest at the top, as in the data, but higher than the data at the bottom and lower in the middle, which is why users' income falls short (Figure 2; see A1).

Validation is Section 5.2 and Table 4, in eight blocks, each of which says why it matters for the experiments. The model comes close on several moments it was not fitted to. The odds that a child of a parent with a SUD acquires one, 1.46, are at the low end of the evidence. Unemployment among households with a SUD is 14.5 percent against 16.2, and households with SMI are 2.64 times as likely as others to use drugs, against 2.44. And it comes close to two pieces of evidence that bear directly on the experiments: the mortality cost of losing housing for households with SMI, 3.6 percentage points against 4.6 in Costantini (2025), and the effect of conditioning housing on abstinence, a ratio of 1.40 against 1.26 in Milby et al. (2005), which A13 and A14 discuss.

The misses that Referee 1 identified in comment 2(c) are smaller but not gone, and Table 4 shows them. The model's homeless are poorer and less often employed than in the data: 21.4 percent are employed, against 46, and their income is 6.5 percent of the average, against 19.1 in Meyer et al. (2024). They are also younger: 37.9 percent are 35 to 44, against 27.2, and 11.5 percent are 55 and over, against 25.9. Users are younger too, with a mean age of 34.6 against 39.6, as well as poorer. The paper says why the age and income of users matter: both policies reach a child through its parent, so the age of users decides how many children their use touches, and the vouchers are means tested, so the lower users sit in the income distribution, the more of them, and of their children, the screen reaches (Block 2 of Section 5.2). And the participation elasticity of drug demand is -1.32, larger in absolute value than the estimates of -0.3 to -0.9; since Treatment First lowers the drug price, a larger price response works against it (Block 5 of Section 5.2).

[Still open.] The rest of Referee 1's comment 2 is answered in my letter to him. One request there is not met: the paper reports no Jacobian of the moments with respect to the parameters and no sensitivity statistic (comment 2(f)).

This is in Section 5.1 (Table 3), Section 5.2 (Table 4 and Figure 2) and Appendix A (Table A1).

A13 Key elasticities the model should match

> *"With respect to the policy evaluations, the key elasticities are (1) the elasticity of drug use to housing access (see R3) and (2) the elasticity of homelessness to drug addiction. The model should highlight these key elasticities in the analysis and show that the model is able to match them."*

Both links are now disciplined by evidence, the first with the trial that Referee 2 pointed to, and each has its own entry in Section 5.1 saying what it does to the two policies.

The elasticity of drug use to housing access. The channel the paper disciplines is recovery: a household with a SUD is less likely to recover in a shelter, by the multiplier μ_H (equation 18). As μ_H falls, housing buys more recovery and Housing First does more to cure a SUD. It is

calibrated to Milby et al. (2005), who randomised homeless adults with a cocaine disorder in treatment into no housing, housing contingent on abstinence, and housing without conditions: housing improved recovery by 47.3 percent, a ratio of 1.47 in the data against 1.45 in the model (Block 4 of Section 5.1). The trial's second contrast, contingent against unconditional housing, is the closest evidence on what Treatment First does to those it houses. It is not targeted, and the model comes close: 1.40 against 1.26 (Table 4, Block 8). The response of drug use to the condition itself is set by the detection rate, against the military's random testing (A11), and its response to the drug price is a validation moment (Table 4, Block 5).

The elasticity of homelessness to a SUD. A SUD makes a job harder to find, by the divisor κ_d^{ue}, and a household out of work longer is likelier to lose its housing: this is the link from the disorder to the street, and it shapes how much Treatment First deters. κ_d^{ue} is calibrated to the share of the homeless with a SUD, 21.7 percent in Gutwinski et al. (2021), 20.2 in the model (Block 2 of Section 5.1), and the unemployment rate it implies for households with a SUD is a validation moment, 14.5 percent against 16.2 (Table 4, Block 2). The same holds for SMI, whose divisor is calibrated to the SMI share of the homeless, 25 percent against 24.7 in the model. Table 5 reports the SUD share of the homeless in every experiment.

[Still open.] The second is not reported as an elasticity. The paper disciplines it through a share and an unemployment rate, and does not compare a response of homelessness to a SUD with an estimate.

This is in Blocks 2 and 4 of Section 5.1 and Blocks 2, 5 and 8 of Section 5.2.

A14 Connect to Costantini and the other empirical work

> *"For example, Constantini (2025) finds for a sample of 300,000 Veterans that Housing First reduces three-year mortality by 4.6 percentage points while Treatment First has no long-term health effects, in contrast with the model simulations of this paper."*

[New result.] The paper now compares the model with Costantini's Housing First estimate. Costantini estimates the effect of each of two programmes of the Department of Veterans Affairs against no housing intervention. His Housing First is the voucher programme the department runs with HUD, and his Treatment First is short term transitional housing run by local contractors. In Block 7 of Section 5.2, with the drug price and π_V held, I compare households with SMI whom Treatment First's revocation puts on the street with the same households had they kept their voucher: losing it raises their three year mortality by about 3.6 percentage points, against the 4.6 by which enrolling in Housing First lowers it among his homeless veterans with mental illness (Table 4). The mortality cost of losing housing in the model is of the same order as the one he measures.

[Still open.] The paper reports no model counterpart to his Treatment First estimate. I have not made one because his estimate compares a stay in transitional housing with no programme at all, while the paper's Treatment First is a different object: the same permanent voucher as Housing First, kept only on condition of sobriety and, for a household with a SUD, of treatment. The model has no time limited programme to set against his finding.

On the contrast you draw with the model, I read his estimates as Section 7 reads the trials: they speak to households already in a bind, within a given environment. In the model those households lose from Treatment First too. With the drug price and π_V held at their Housing First levels, as in a trial, 74 percent of the households that have a SUD when the reform lands are worse off under Treatment First, and 67 percent still are when both clear. What reverses the comparison

lies outside what such designs observe: the households the condition deters from starting to use, the vouchers its savings buy for others, and the children (Section 7).

On the other papers you name: Abramson (2026) is now cited in Section 2, on how eviction policy changes who becomes homeless. **[Still open.]** Cohen (2024), Brounstein and Wieselthier (2026) and Humphries et al. (2026) are not cited.

On your final question in this paragraph, whether a SUD has direct effects on productivity, see A20.

This is in Section 2, Block 7 of Section 5.2 (Table 4) and Section 7.

A15 The fiscal cost of homelessness looks high

> *"The fiscal cost of homelessness for the United States is also estimated in recent work of Abramson and van Nieuwerburgh (forthcoming). It would be valuable to provide a comparison of their figures to the CEA estimates or provide robustness analysis with respect to these estimates of the fiscal costs. The current estimate appears high (see R3)."*

The fiscal cost of homelessness is no longer a parameter of the model, and neither is the fiscal cost of a SUD that the previous draft took from the Council of Economic Advisers. A household in a shelter costs the government nothing beyond the transfers any household with its income receives: the budget (equation 26, Section 4.11) pays UI, social security, food assistance, vouchers, drug tests and treatment, and has no item for the shelter. The only public cost tied to a SUD is treatment, \$9,426 a year for each household that takes it up (Block 4 of Section 5.1). So neither the previous draft's figures nor Abramson and Van Nieuwerburgh's enter the paper. This also answers Referee 2's remark in comment C6 that the previous draft's cost of an unhoused household was high and exceeded the rent on the smallest unit: in the new model it is zero.

[Still open.] For the same reason, the paper does not compare Abramson and Van Nieuwerburgh's figures with those of the Council of Economic Advisers, does not cite their paper, and has no robustness run with a fiscal cost of homelessness: there is no such cost in the model for either figure to discipline. The paper does not show how the results would change with one. My reading is that leaving it out does not favour Treatment First. In the main experiment, Treatment First lowers homelessness by 11 percent and the share of households with a SUD by 19 percent in the long run, and homelessness does not rise in any year of the main transition (Sections 6.2 and 6.4); at those allocations, a cost per homeless household or per household with a SUD would add to what Treatment First saves the budget.

This is in Section 4.11.

A16 Where does 37 percent of homeless with SUD come from?

> *"It is not clear where the statistic that 37 percent of homeless people are experiencing SUD comes from. This seems very high and will also depend greatly on the definition of homelessness . . . At a minimum, it should be clarified where this number is coming from and what definition of homelessness the author is targeting."*

[Conceded.] You were right to be suspicious, and the number is no longer used. The previous draft took it as the midpoint of a range of substance abuse rates among homeless adults in New York City and Philadelphia (Kuhn and Culhane, 1998), a measure of substance abuse in general that varied with the population and the definition. The target is now the prevalence of drug use

disorders among homeless people in high income countries in the meta analysis of Gutwinski et al. (2021), 21.7 percent. It calibrates how much harder a SUD makes it to find a job, and the model gives 20.2 percent (Table 3, Block 2).

On the definition: the homeless state is literal homelessness, sleeping rough or in an emergency shelter (Section 4.5). Doubling up is not a state of the model. The homelessness rate is pinned not to a point but to a band, 0.40 to 1.00 percent of households: the floor is HUD's 2023 PiT count, which counts people in shelters and on the street on a single night, and the ceiling is the share homeless at some point over a year, from Burt et al. (2001). The model gives 0.62 percent. The other moments of the homeless come from HUD's 2024 PiT count, for their ages, and from Meyer et al. (2024), for their employment and income (Table 4, Block 1).

This is in Section 4.5, Block 2 of Section 5.1 and Block 1 of Section 5.2.

Writing

A17 The calibration section reads as a long list

> *"Both the model parameterization and the calibration are rather thin. The section is monotonically written as a longlist of targets. . . . estimates appear to come from different decades, and it is often not clear which data waves are used (such as the SCF), making the paper impossible to replicate . . . there seems to be no distinction between parameters that are standard in the literature, versus those that are new to the paper. From the references, for example, it is not clear that the 10-year recovery rates for alcoholism (Vaillant, 1995) would apply to substance use disorder for the homeless."*

Rewritten, along the lines you set out, with one exception, Vaillant, which is still open.

Insight rather than a list. Section 5.1 groups the 26 parameters that carry the paper's story into six blocks by the mechanism they work through: who uses drugs, the costs of homelessness and vouchers, the SMI chain, recovery and treatment, the externalities, and the drug market. Each block opens with what it decides for the policies, and each parameter's entry runs in the same order: what the parameter controls, how it bears on Treatment First, Housing First or drug use, what happens as it rises, and only then its value, its moment and its source. The validation in Section 5.2 is organised the same way, each block saying why it matters for the experiments.

Standard against new. The 33 parameters common to most life cycle models, for preferences, the rental ladder, earnings and employment, survival and the onset of SMI, interest and taxes, social security and programme rules, and the rest of the drug market, are in Appendix A with Table A1, separate from the 26 in Table 3. Every row of both tables says whether the parameter is set externally or calibrated internally, and for the internal ones gives the data and the model value.

Vintages and replication. The surveys are named with their waves: NSDUH 2024, the 2022 SCF, HUD's PiT counts of 2023 and 2024, the 2024 Consumer Expenditure Survey, and the Current Population Survey over 2014 to 2024, among others. Estimates taken from studies keep the study's date, and some are old, Vaillant (1995), Burt et al. (2001) and Roebuck et al. (2003) among them. The replication package's `data/DATA_APPENDIX.md` documents the dataset, year, universe and computation behind every estimate, and the package carries all the datasets, so nothing has to be downloaded (Section 5).

Vaillant. [**Still open.**] You are right that a ten year remission rate for alcoholism is not obviously the remission rate of a drug use disorder among the homeless, and the paper still uses it. The baseline annual chance that a housed household with a SUD recovers, 0.025, is the hazard implied by Vaillant's ten year remission rate (Block 4 of Section 5.1), as in the previous draft, and the paper gives no further justification for applying it to drugs. What has changed is recovery in a shelter: it is that baseline scaled by μ_H, which is now calibrated to Milby et al. (2005), whose participants were homeless adults with a cocaine disorder in treatment (A13).

This is in Section 5 and Appendix A.

A18 Fewer counterfactuals in the body

> *"In terms of the policy analysis, ideally there would be fewer counterfactual analysis in the body of the paper to convey the main message. ... The first and third experiment in this case seem to be most relevant singling out what is the better policy under rationed quantities and non-rationed settings."*

Done in part; the difference from your suggestion is stated plainly below. The paper now asks one question, whether the existing rationed programme should require sobriety, and has three experiments (Section 6). The first removes the externalities on children and asks whether moral hazard alone justifies Treatment First; it does not. The second introduces Treatment First in the full model in steps, letting first π_V and then the drug price clear, so that each general equilibrium effect is shown on its own; the last step is the main experiment. Both are in Table 5. The third is the transition from Housing First to Treatment First, with both clearing every period (Figure 3). The robustness runs are reported in a sentence or a footnote each: half the detection rate, a higher weight on the child, no earnings penalty, no response through treatment, and a homelessness disamenity. The alternative transitions, in which households with a SUD cannot stop using, stay in the body rather than an appendix, in a short section with one table (Section 6.5, Table 7), because the third lesson of Section 7 rests on them.

[**Still open.**] No experiment removes the rationing. Every experiment keeps the programme rationed, so the previous draft's third experiment, Treatment First against Housing First with universal vouchers, is not in the paper. I left it out because the paper asks the question the executive order raises, whether the existing, rationed programme should require sobriety (Section 1). The size of the programme still moves in the experiments, because π_V spends what the screen saves: in the main experiment it rises from 6.75 to 7.80 percent.

This is in Section 6.

A19 Language

> *"The language of 'addicted' seems incorrect. The author should modify throughout something to suffering from substance use disorder."*

Done. The paper speaks of households that use drugs and of households with a SUD throughout the text, the tables and the figures. The word survives only in the titles of cited works.

This runs through the whole paper.

A20 Direct productivity effects of substance use disorder

> *"Incidentally, are there direct productivity effects of substance use addiction on productivity?"*

[Still open.] Not as a direct effect on the user's own productivity: a SUD does not lower the wage of a household that works. It lowers the user's earnings through employment instead. An unemployed household with a SUD finds work at the baseline rate divided by κ_d^{ue}, so its spells out of work last longer (Section 4.8). How much this costs is checked against the data: the unemployment rate of households with a SUD is 14.5 percent in the model against 16.2 in NSDUH 2024 (Table 4, Block 2).

The productivity effect the model does have is on the next generation: a child whose parent had a SUD while it lived at home starts adult life with its productivity lowered by $\delta_d = 0.24$, for life (A6). This is the earnings externality, worth 0.46 percent of a newborn's lifetime consumption in the main experiment, 18 percent of the gain (Table 6). The paper notes that the ranking of the two policies does not rest on the penalty's size (footnote 30), and Treatment First still raises welfare with the penalty set to zero (footnote 5).

This is in Section 4.8, Block 5 of Section 5.1 and Section 6.3.
